AMERICAN JOURNAL OF PSYCHIATRY

INFORMATION FOR CONTRIBUTORS

Manuscripts—The *original* manuscripts of papers read at the annual meetings of the Association should be deposited with the Secretary during the meetings, or sent to the New York office promptly afterward. Do not deposit carbon copies.

Papers read at the annual meetings become the property of the Association. Not all papers read, however, can be published in the *JOURNAL*, and authors wishing to publish in other vehicles will first secure from the Editor the release of their manuscripts.

Papers will not be accepted for the annual program if they have been previously read at other meetings or if they have been already published.

Papers contributed during the year (not on the annual program) should be sent to the Editor, Dr. Clarence B. Farrar, 200 St. Clair Avenue, West, Toronto 7, Ontario, Canada.

Style—Manuscripts should be typewritten, double spaced, on one side of the paper. They must be prepared in conformity with the general style of The American Journal of Psychiatry. Retain a carbon copy of manuscript and duplicates of tables, figures, etc., for use should the originals be lost in the mails.

Multiple Authorship—The number of names listed as authors should be kept to a minimum, others collaborating being shown in a footnote.

Illustrations—Authors will be asked to meet printer's costs of reproducing illustrative material. Copy for illustrations cannot be accepted unless properly prepared for reproductions. Wherever possible, drawings and charts should be made with India ink for photographic reproduction as zinc etchings. Photographs for halftone reproduction should be glossy prints. Illustrations should be as small as possible without sacrificing important detail. Redrawing or preparing illustrations to make them suitable for photographic reproduction will be charged to author.

Authors' Corrections in Proofs—Corrections, additions or deletions made by authors are to be charged to them. These alterations are charged on a time basis at the rate of \$7.00 per hour. Proper editing of original manuscript is important to avoid the expense of correction.

Tables—Tables should be typed on separate sheets. Tables are much more expensive to set than text material and should be used only where necessary to clarify important points. Authors will be asked to defray cost of excessive tabular material.

References—References should be assembled according to author in a terminal bibliography, referred to in text by numbers in parentheses. Bibliographical material should be typed in accordance with the following style for journals and books respectively:

1. Vander Veer, A. H., and Reese, H. H. : *Am. J. Psychiat.*, 95 : 271, Sept. 1938.
2. Hess, W. R. : *Diencephalon*. New York : Grune & Stratton, 1954.

Abbreviations should conform to the style used in the *Quarterly Cumulative Index Medicus*.

The American Journal of Psychiatry, formerly The American Journal of Insanity, the official organ of The American Psychiatric Association, was founded in 1844. It is published monthly, the volumes beginning with the July number.

Articles appearing in this Journal do not necessarily reflect the official attitude of The American Psychiatric Association or of the Editorial Board.

The subscription rates are \$12.00 to the volume: Canadian subscriptions \$12.50; foreign subscriptions, \$13.00, including postage. Rates to medical students, junior and senior internes, residents in training during their first, second, or third training year, and also to graduate students in psychology, psychiatric social work, and psychiatric nursing, \$5.00 (Canada \$5.50). Single issues, \$1.50. Copyright 1960 by The American Psychiatric Association.

Office of Publication, 10 Allen St., P.O. Box 832, Hanover, N. H.

Business communications, remittances and subscription should be addressed to The American Psychiatric Association, 10 Allen St., P.O. Box 832, Hanover, N. H., or to 1270 Avenue of the Americas, New York 20, N. Y.

Editorial communications, books for review, and exchanges should be addressed to the Editor, Dr. Clarence B. Farrar, 200 St. Clair Avenue, West, Toronto 7, Ontario, Canada.

Second class postage paid at Hanover, New Hampshire.

CONTENTS OF VOLUME 119

JULY, 1962

PRESIDENTIAL ADDRESS, <i>Walter E. Barton</i> . . .	1	Olfactory Changes in Schizophrenia. <i>A. Hofer, and H. Osmond</i> . . .	72
WALTER E. BARTON. <i>L. P. Alexander</i> . . .	16	Clinical Evaluation of Carphenazine and Piperacetazine in Previously Placebo-Treated Chronic Schizophrenics. <i>Bessie Claffey, Lester H. Margolis, and William Mandel</i> . . .	75
CLINICAL-STATISTICAL ANALYSIS OF POPULATION CHANGES IN NEW YORK STATE MENTAL HOSPITALS SINCE INTRODUCTION OF PSYCHOTROPIC DRUGS. <i>Henry Brill, and Robert E. Patton</i> . . .	20	CASE REPORTS : . . .	
AN APPROACH TO THE EFFECT OF ATARAXIC DRUGS ON HOSPITAL RELEASE RATES. <i>Leon J. Epstein, Richard D. Morgan, and Lynn Reynolds</i> . . .	36	Jaundice Following Thioridazine Administration. <i>Stanley L. Block</i> . . .	77
A SUMMARY DESCRIPTION OF FIFTY "NORMAL" WHITE MALES. <i>Jules Golden, Nathan Mandel, Bernard C. Glueck, Jr., and Zetta Feder</i> . . .	48	Schizophrenia in a Patient with Gaucher's Disease Treated with Modified ECT. <i>James F. Suess, and Harry Little</i> . . .	78
AMNESIA : A CLINICAL STUDY OF NINETY-EIGHT CASES. <i>Theodore A. Kiersch</i> . . .	57	Efficacy of ECT Following Prolonged Use of Psychotropic Drugs. <i>Kurt Witton</i> . . .	79
MODEL PSYCHOSES AND SCHIZOPHRENIA. <i>Elliot D. Luby, Jacques S. Gottlieb, Bertram D. Cohen, Gerald Rosenbaum, and Edward F. Domino</i> . . .	61	HISTORICAL NOTE : . . .	
CLINICAL NOTES : . . .		Hysterical Aphonia. <i>Murray S. Wilson</i> . . .	80
A Comparison of a Recently Introduced Phenothiazine Derivative (MDS 92) and a Placebo in Chronically Ill Mental Patients. <i>A. Barron, Barbara Beckering, Lester H. Rudy, and Jackson A. Smith</i> . . .	68	COMMENTS : . . .	
The Prediction of Response to Tranylcypromine plus Trifluoperazine by the MMPI. <i>Edward S. Sulzer, and Burtrum C. Schiele</i> . . .	69	Toronto Meeting Highlights . . .	81
Comparison of Butyrylperazine and Trifluoperazine in Chronic Schizophrenic Subjects. <i>William Mandel, and Philip Evans</i> . . .	70	CORRESPONDENCE : . . .	
Fluphenazine in Chronic Refractory Schizophrenics. <i>N. E. Stratas</i> . . .	72	Communication Amongst Automata . . .	84
		Phenmetrazine HCL Addiction . . .	84

Charles E. Barton M.D.

PRESIDENTIAL ADDRESS

PSYCHIATRY IN TRANSITION¹

WALTER E. BARTON, M.D.

Medicine's largest task is to give meaning to the longer life it has made possible.

—Dana Farnsworth.

Great achievements for human welfare and effective programs of social action have often been made by crusading individuals. Committees, commissions, and associations are less effective prodders of the social conscience. The American Psychiatric Association from its formation has been a vigorous exception. The improvement of the care and treatment of the mentally ill and furthering interests in the maintenance and advancement of standards of hospitals for mental disorders have been objectives of our association through the years.

At the 25th meeting of the association, held in Toronto on June 6, 1871 (the 13th² was the first meeting held in Canada) Dr. John S. Butler, President of the American Psychiatric Association (he had been the first superintendent of the Boston State Hospital), addressed the 37 members and guests present. The highlights of that meeting were a resolution calling for the instruction in psychiatry in medical schools; the decision not to adopt the resolution proposed by the American Medical Association's House of Delegates to join in "intimate union" and in a common meeting (1); and the long discussion of the proper size of mental hospitals. A resolution was finally adopted permitting an increase to 600 patients(2).

Today at the 118th annual meeting of this association, back in Toronto 90 years later, another superintendent of the Boston State Hospital addresses you. The size of mental hospitals is an area of continuing

disagreement. The challenge of effecting better care and treatment of the hospitalized mentally ill remains.

As president of the association, I have made *Action for Mental Health*(3) the central theme in my administration. I firmly believe that the greatest opportunity given this generation to make a sweeping advance in the entire field of psychiatry is through the implementation of the recommendations of the Joint Commission on Mental Illness and Health. Not only will adoption of the action plan be the greatest achievement in our lifetime in the United States, but it will have undoubted impact on the development of Canadian psychiatry as well.

The Joint Commission on Mental Illness and Health developed at a time when advances in treatment and new methods of management made possible new directions. The public, too, was aware of changes and was beginning to demand good psychiatric treatment. The fact that eighty percent of all psychiatrists were in private practice made community psychiatry possible. These trends were propitious to the establishment of the commission. Most members, I hope, will have read the excellent position statement adopted by the Council of the American Psychiatric Association and released on January 15, 1962(4). It urged support of the *Action for Mental Health* Program.

Nearly all psychiatrists will support the major recommendations urged by the Joint Commission:

1. *Expansion of research.* More effective treatment of mental illness and the means for preventing it awaits knowledge derived from research. "The mental health sciences address themselves to the alleviation of a complex of biological, psychological, and social problems that have plagued man throughout his history; mental health scientists face this task with an incredibly small

¹ Presidential Address delivered at the 118th annual meeting of The American Psychiatric Association, Toronto, Canada, May 7-11, 1962.

² Russells Hotel, Quebec City—28 persons attended, 3 from Canada.

fund of knowledge about causes and cures" (3). Advocated is a balanced and diversified portfolio of basic and applied research with more support of long term programs rather than 2- or 3-year projects and the expanded support of men who will train for investigative careers.

2. *Application of knowledge.* There is need to press hard so that we may apply what we already know. If the knowledge at hand and that derived from research is to be applied, the deepening shortages in professional manpower must be offset. We are caught with the need to expand services and we lack the personnel to do so. The deficit in manpower within the health services is in part due to the fierce competition for the top students graduating from college. The bright students who drop out must be stimulated to complete high school. Opportunity and encouragement should follow to enter and to finish college. The science manpower pool, from which medicine, psychiatry, and the associated health professions draw their recruits, must be filled through a national effort. Shortages in scientific and health services will increase, we are warned, as the population expands. This will occur before recruitment can hopefully solve the long range demands for professional help. This leaves us two hard choices for the present: Better utilization of the few trained personnel at hand; the wider use of other persons than those professionally qualified. The more efficient use of psychiatrists and of associated specialists calls for bold experimentation in new methods of providing service. New organization plans and efficient application of the technique of work simplification and work performance studies are desirable. Overlapping, duplicating, and wasteful practices must be eliminated.

3. *The support of community psychiatry.* In a few years the proportion of psychiatrists in hospital and in private practice has reversed. General hospital and clinic facilities for mental patients have been expanding. "Immediate professional attention should be provided in the community for persons at the onset of acute mental illness" (3). Emergencies must be met. The center that provides outpatient service, day hospitalization, and a home visiting team may

be the decade's greatest advance in service. Much talk about community psychiatry replacing mental hospitals is speculative. The great majority of psychiatric patients seen by the private practitioner in his office, those seen in the outpatient department and in the general hospital are not those with the serious forms of mental illnesses that cause the community distress. The retarded and the psychotic are avoided by many men in practice and by community agencies. The psychoses are the hard core of the mental illness problem, along with mental retardation, the aged, alcoholism, and mentally ill offenders. While the number of individuals with psychoses accepted for treatment in general hospital has increased from less than 15%, it is still under 25% of the total number of patients admitted for psychiatric treatment.

The years ahead will develop and extend a community psychiatry which provides treatment for the psychoses at home, in the psychiatrists' office and in the general hospital.

The willingness to change, the availability of resources in manpower and the ability to pay the increased cost of care are presumed in support of the trend toward care of the more serious mental disorders in the community. The public mental hospital operates at an average cost of \$5.00 per patient day. Arguments have justified trebling the figure in ten years to \$15.00 per patient day. In 1962 the general hospital must collect over \$30.00 per day to meet expenses and in a decade predictions indicate a day of patient care will cost a staggering \$60.00. Not many of the families who form the clientele of the Boston State Hospital could afford care at that rate.

4. *Shared financial support.* In a free society, treatment under private auspices is vital. Voluntary insurance plans can lighten the burden of expense. General hospitals, however, cannot afford to provide long and costly care for indigent persons. The states and provinces alone are unable to "double their expenditures in the next five years" (3) without help. Private enterprise, local effort and insurance schemes must cooperate to meet some of the increased costs. As the principal resources for taxation are at the disposal of the federal government, the

Joint Commission calls for a major assist to program development. Federal support to supplement state and private resources is imperative to the translation into action of the needs in research, training and service.

Some fear that intervention by the federal government will destroy local initiative and will usurp program planning. The Joint Commission asks for the creation of an Advisory Committee to guide federal and local cooperation. Obviously, controls are necessary when public money is expended. With remote central control the danger is forced uniformity and regimented mediocrity. Without controls funds may be used for patronage or the perpetuation of outmoded institutions. Who, then, is the best judge of how new money should be spent? The integrity and wisdom of local planners must either be assumed or the approval of a government agency obtained as a prelude to a matching grant.

The United States provides financial aid to many foreign countries and believes it to be within the means of the people. The country can afford a five billion dollar farm surplus program; it can afford the luxury of preparation for a visit to the moon. The United States can also afford a program of conservation of human resources, if the people want it.

One is not expected to agree with all of the statements made by the Joint Commission on Mental Illness and Health. Areas of disagreement have been touched upon in commentaries and discussed in dissents to the report(5). I would speak about three controversial areas. Who shall treat the mentally ill? Can all psychiatric illnesses be treated in general hospitals? How should the APA "make special efforts to explore, understand, and transmit to its members an accurate perception of the public's image of the psychiatrist?"(3).

1. Who shall treat the mentally ill?

Because 71% of individuals who seek help for an emotional or psychological problem go to the clergy or to a physician, it makes good sense to assist these helping professions to increase their effectiveness. It is also necessary to help them recognize serious disorders and to increase their awareness of the significance of failure to respond. The seriously ill and the refractory patient can

then be speedily referred to the nearest psychiatrist or psychiatric facility.

We have already said that new programs in general hospitals and in mental health centers must be staffed from the existing pool of professional workers. Greater effort has also been urged to meet the communities' needs for assistance with its major problems—the retarded, the delinquent, the offender, the alcoholic and the aged. The forthcoming Graduate Training Conference sponsored by the American Psychiatric Association³ and the Canadian Society will explore the unmet needs of psychiatry and other aspects of training of residents in December 1962. (I have the honor, shared with Dr. Malamud, of being the Co-Chairman of that important conference.)

More help to meet expanding demands can be expected by challenging both psychiatrists in private practice and in mental hospitals and clinics to change their roles. Specialists in private practice must help treat psychotics, and hospital psychiatrists must help treat patients in the community. Both must train and supervise others who multiply their effectiveness by carrying out treatment procedures. A defect in training presently produces medical men who are uncomfortable in these situations. But role change alone will not meet the demands for service. The task is greater than the resources at hand. It is for this reason that I see as inevitable the delegation of more responsibility to the helping professions.

The nurse clinical specialist can serve the individual and the group of patients in hospital, in the day hospital, in the home treatment service, and in the aftercare clinic. Nurses may welcome the more exciting challenge these new roles offer in contrast to the frustrations of ward administration in a public mental hospital. Nurses, social workers and psychologists (with training, practical experience and demonstrable competence), under the auspices of recognized mental health agencies, should be permitted to treat patients with short term psychotherapy(3).

The principle of diagnosis and evaluation

³ Conference expenses, in the United States, will be met by a grant from the National Institute of Mental Health.

of mental illness by medical experts in psychiatry is not to be abrogated. Medical responsibility is fundamental in the management of mental illness. Many aspects of treatment, however, can be delegated with safety to competent associates. We have been happy through the years with the team relationships in the mental health clinic. We are distressed when attempts are made to separate out psychotherapy from the main stream of medicine as the basis for independent private practice by *any* professional group. Symptoms of stress and disturbed behavior frequently develop in the setting of physiological and pathological disorders. The patient with anxiety due to hyperthyroidism or one, for example, with a depression following steroid administration must be protected from persons who believe all symptoms of mental illness are social disorders and all mental illness treatable by psychotherapy alone.

2. Can *all* psychiatric illnesses be treated in general hospitals?

This question is guaranteed to arouse bitter disputes. Some say *all* can be treated in general hospitals and that the time has come to abandon public mental hospitals as obsolete and unnecessary. It is probably true that with a selective admission policy and an excellent intensive treatment program, the number of patients with psychosis who require further care in a mental hospital can be reduced to less than 10%. Is it to be assumed that the general hospital will also provide care for the brain damaged, the chronic alcoholic patient, the sexual deviate, the chronic neurological patient and the aged who require care in chair or bed for an indefinite period? If so, it may prove extravagant to attempt prolonged care in expensive new medical facilities where costs of 30 to 40 dollars per day are not unusual.

The notion that the present public mental hospitals should be converted to chronic disease hospitals has met with opposition from all sides. Some say the idea represents another form of rejection of the mentally ill with psychosis. Before the Joint Commission's recommendation that the large public mental hospital be converted into a chronic disease hospital is accepted, there should be some experimentation with different organ-

izational structures and evaluation of their operation.

For example, the common elements in the response to the process of rehabilitation might be studied in a center grouping together chronic medical, neurological and psychiatric diseases for treatment under experts in that field. Another example could break up a large public mental hospital into separate hospitals, each with its own mission and its own staff. The complex could be known as a hospital center and share supportive utilities and services. The independent units could include: a trauma section for all emergencies, an acute intensive treatment hospital, a geriatric hospital, a rehabilitation hospital, and a long stay annex for the care of chronic diseases. I would emphasize that the mental hospital or the hospital center are only a part of the total mental health plan of today and tomorrow.

This time around, let us concentrate on brains and people before we build new multi-million dollar structures. It is best, perhaps, to sponsor the functional growth first and let the structure be built in the next decade to support the function that evolves. We may also discover that the public mental hospital still has an important place in the treatment continuum of the mentally ill. I firmly believe that it does and that it merits the necessary financial support to carry out its essential mission.

Let us build no more big isolated mental hospitals as we concentrate on the development of community psychiatric services. The part time staff, the open staff, and the associated specialties required for the practice of medicine work more effectively in the mental hospital and in the community general hospital and its clinics when distance doesn't cause the loss of precious man hours. Distance is important also to therapy with families, day care, aftercare, and in maintaining liaison during the transition from hospital to home.

3. How should the APA "make specific efforts to explore, understand, and transmit to its members an accurate perception of the public image of the psychiatrist?" (3).

The image of the psychiatrist is not a portrait of an idealized being transmitted via the mass media to the many publics. Image building can only be aided by the

public relations man.⁴ What a man is, what he believes in, and what he does creates an impression upon those he serves, those associated with him, and those who behold the relationship. It is the projection of the doer and the deeds that is the image.

Why should American psychiatry be concerned with its image? Let's first take a critical look at the things people say they don't like in us:

A psychiatrist is a physician, yet he often does not behave like one. He may excuse himself from helping with hospital emergencies when there is no else available; he may not attend medical meetings as other specialists do. The psychiatrist may not come to the aid of a physician with a mentally ill patient. The type of patient, his inability to come to the psychiatrist's office, or a full schedule for weeks ahead are excuses given for not offering help. This leaves the physician with a poor opinion of psychiatrists and of their usefulness as consultants. Some psychiatrists charge a medical colleague patient or a physician's family for consultation and for short term treatment. Many psychiatrists desire exemption from the centuries old ethical traditions of no charge to doctors and their immediate families. Massive medical opinion is mobilized against psychiatry for its stand that all should pay for prolonged intensive psychotherapy.

The public is suspicious of omnipotence in physicians. Irritation develops when the psychiatrist declines to speak with the family physician about a patient or with his family. Society's cherished value systems are not to be trampled upon and there is fear that some psychiatrists do so.

The cartoonist's characterization is that of the psychiatrist who sits and dozes at the head of a couch on which a wealthy neurotic woman reclines reciting trivia.

There can be a very different shadow

⁴ With the restriction of time and space in a presentation of this sort it is not possible to develop the important themes of public education and public information in image building. Translation of professional jargon into understandable language is one of the tasks of the public relations specialist. The PR man also helps us interpret aims and needs to our many publics and give necessary assistance to get the public support essential to sustain a psychiatric program.

cast by the average psychiatrist. The new image of the psychiatrist would stress ability as a well trained physician with the technical knowledge and expertness required of a specialist. As a consultant, he would function as other specialists when called by a colleague. A major part of his practice might well be in the office, clinic, general and mental hospital. He would be no stranger in the home and would be available to meet psychiatric emergencies. A generalist in the field of psychiatry, he would accept for treatment those with major mental illness.

Patient oriented, available for help and attuned to community needs, the psychiatrist devoted to his profession kindles enthusiasm and serves as a model for identification to the young man seeking a career. The new image would be incomplete without a positive program of medical leadership in pursuit of excellence. This requires the courage to expose one's own shortcomings. When one sidesteps deficiencies it may give the impression of condoning wrongs. Lastly, research is the high adventure in today's scientific world. Psychiatry must develop men who can take their place alongside of the biochemist, social scientist and neurophysiologist.

NATIONAL AND INTERNATIONAL MATTERS

The emphasis that I have given to the report, *Action for Mental Health*, has brought into sharp focus the national concern of the American Psychiatric Association. The Joint Commission on Mental Illness and Health is of importance to United States members. Through the years, as the APA has grown in numbers and in strength, it has frequently presented its views before Congress. Its concern with matters of interest to United States citizens has absorbed most of its energies. At the same moment in history, in the sixties, nationalism in all countries has increased. Canada, too, has moved apart from the close relationship it once felt toward the United States.

Prior to 1945, with the exception of the few in Toronto and Montreal, nearly all Canadian psychiatrists worked in mental hospitals. In the past 17 years, all 10 universities in Canada have developed depart-

ments of psychiatry, all provinces have expanded psychiatric services and private practice has extended to the large cities. The new elements found expression in the Canadian Psychiatric Association.

The dilemma of national and transitional APA interests has been the subject of other presidential addresses. It is a continuing concern of a handful of statesmen within the association. The need for discussion exists. We should steer a course in international policy that avoids the shoals of estrangement. A forthright report of the liaison committee with the Canadian Psychiatric Association directed attention last year to the separateness. I was startled by the import of an action by the Canadian Psychiatric Association making Honorary Members of two past presidents of the APA. Last year the Committee on Constitution and By-Laws and the Membership Committee were concerned with association boundaries. Why not admit *all* the Americas? Some friends in the Philippines might also wish to join us. Would they be invited?

The double role of national and international interests gets most involved and troublesome. Great tact and diplomacy is required to deal with problems which inevitably arise when a large group offers to absorb a smaller one which has local pride and a different tradition(6). Whenever the formation of a District Branch outside the United States is under discussion, conflicting loyalties emerge.

Canadians and American are quite separate in their national interests. Canadians relate to their own local association in each province and all are affiliated with the Canadian Psychiatric Association. The long tradition of autonomy in Quebec has kept its affiliation to a token; while ties to the central organization vary elsewhere, they are growing stronger each year. The concern of many Canadian psychiatrists is directed toward the Federal Hospitalization Act which will pay for the cost of care for psychiatric patients in psychiatric divisions of general hospitals. The act does not cover care in mental hospitals where the cost remains the responsibility of the Provincial government. The need to develop mental health services in Canada is another press-

ing matter before the Royal Commission on Health Services(7). The national survey being made by a committee on Mental Health Services in Canada under Dr. J. S. Tyhurst is an action to fill the need(8). Neither United States members nor the association as a whole have taken any action on these important political-medical questions. It probably never occurred to a Canadian member that the APA should express an official view, for the Canadian Psychiatric Association is their acknowledged voice in government.

Members in the United States are properly concerned with the government's policy on disarmament and on civil defense as well as with the Joint Commission on Mental Illness and Health. We are active on behalf of the Kerr-Mills medical care of the aged or in clarifying the testamentary capacity of clinical psychologists before the courts.

The time has come to give thoughtful consideration to the best solutions to national and international responsibilities of psychiatry. If Canadians feel their interests are better served by leadership arising from their Canadian Psychiatric Association, then the membership of the American Psychiatric Association should accept this reality graciously. To make it possible to discuss the matter frankly without feelings of guilt, I am proposing that the American Psychiatric Association become the national organization representing psychiatry in the United States. In this view members from Mexico, Central and South Americas might be expected to look to their own national organizations also for leadership in psychiatry.

Having recommended an organizational break up of the transnational structure of our Association in favor of a stronger chain of national organizations, in which the American Psychiatric Association would be in structure, as it has been in most of its functions, the national association for the United States, I would at the same time work for a more diplomatic, and mutually respectful, mode of participation with other national units on the American continent. For this purpose, the role of the committee on International Relations should be greatly strengthened. It must be much more than

a committee to honor guests at the annual meeting. Under vigorous leadership, this committee should develop policy and recommend action by the Association in relation to sister national societies and in world affairs. The resources of the American Psychiatric Association, reconstituted as the national association for the United States, should be made available to other psychiatric societies on this continent, without any arrogant presumption of hegemony, in a spirit of mutual neighborly respect and cooperation. We in the United States might learn much from the experiences and the thinking of our Latin American friends by the improvement of communication and rapport. I foresee, as eminently desirable, the formation of permanent sub-committees of the International Relations Committee, in liaison with: the Canadian Psychiatric Association, the Mexican Psychiatric Association, the Latin American Psychiatric Association, the World Psychiatric Association.

Such development may proceed over several years if Canadian members of the APA choose to ask that their allegiance to the C.P.A. be recognized. The APA may then respond by action to affirm its national status. The first permanent liaison sub-committee, that with Canada, must then be strengthened if this step is completed. Other steps should follow at the appropriate time. The World Psychiatric Association, a newcomer, was born in 1961 in Montreal to represent psychiatry on the world scene. It would be appropriate to activate a permanent subcommittee in liaison with it, for there are significant international matters of concern to psychiatrists now quite apart from stimulating vacation travel to scientific assemblies.

Communication of research findings in various languages, retrieval techniques for literature in libraries, standard building, commonality of laws to abolish discrimination that would exclude the mentally ill from benefits afforded the physically ill, the conservation of human resources, and the position of psychiatry in support of disarmament in all nations and toward the reduction of world tensions are but a few of the international interests of psychiatry.

Once the break up of the APA is effected into national components, I would

expect international relationships to move forward more smoothly than they do now. A Pan-American Section in the World Psychiatric Association, as a federation of national organizations, might be expected to develop rapidly and to hold regional conferences, once the fear of domination and colonization were removed.

Under the proposal, the APA would continue to offer assistance and its resources, upon recommendation of the Committee on International Relations, when invited to do so by neighbors. The association would seek advice from its honorary and corresponding members in many lands. Canadian and Latin American psychiatrists would be invited to participate in the scientific and social aspects of the annual meetings. The Journal could keep members posted with events of interest by way of national correspondents.

Shed no tears for the recommended separation of the American Psychiatric Association as we meet with our brothers together in a happy occasion in Toronto that expresses our common interests. Canadians and Americans discussed plans for mental hospitals together when the association was formed over 100 years ago. It was assumed that research, training, and standard building would always be the basis for joint membership. We can be proud of the fruitful years of sharing.

We have served our members well. Medical care has become an exportable asset and an instrument of foreign policy. As the world has constricted, ideological positions have threatened the informality of friendly neighboring relationships. Each local group prefers to do its own work, carry out its own training and express its own individuality. If a changed role is chosen, the American Psychiatric Association will still use its resources as a powerful force for good on the national scene, will give assistance to countries who request it, and will accept its full measure of responsibility in international matters.

Now I wish to turn to the third major topic in this address. Last year Dr. Kety(9) called attention to the strange behavior of the psychiatrist once he believes he understands a mental disorder reasonably well and explains the etiology and pathogenesis of a disorder. When this has been done, the

disorder ceases to be a part of psychiatry. "It would appear," Dr. Kety said, "that only mysterious ailments are psychiatric in nature."

"The training of so many psychiatrists in this generation is so predominantly in psychodynamic theory to the exclusion of the biological and even the social sciences that he feels uncertain or aloof in the management of disorders in which the important factors in etiology are biochemical or microbial" (9). This aversion is startlingly illustrated by the avoidance, in training centers and by residents, of the senile and arteriosclerotic disorders. Mental illness is the number one health problem and of all mental disorders requiring hospital care, the patient over 65 forms the largest group. The magnitude of the defect in training and the disinterest in problems of aging compels me to emphasize psychiatry's concern.

PSYCHIATRY'S CONCERN FOR THE AGED

Social and Political Action. Social change often results from political action. Social and political issues have a relevance for medicine when they concern matters of health, including the control of disease. The Housing Act and the Kerr-Mills Medical Act for the Aged Law were two important accomplishments of the 1961 United States Congress. Currently, President Kennedy seeks support for an amendment to the Social Security law that will make the Federal Government responsible for payments for hospitalization and nursing home care, outpatient and diagnostic services for those eligible for Social Security retirement or survivorship payments. Senate Bill 2779 would establish the United States Commission for Aging. It proposes to develop policy and legislation to make possible grants for the development of programs for the care of the aged.

I have repeatedly stressed, in the Journal pages and in my talks, the importance of taking a position on vital social issues. In a large organization the rapid accumulation of facts upon which to base a decision and the translation of policy into effective action are not easily accomplished. The appropriate committees must be prepared to offer speedy assistance as need arises in between their scheduled annual meetings. The APA

Central Office staff members are willing fact gatherers. With basic information in hand, the Council or its Executive Committee or the President can state an official position. The Public Information Committee and staff experts disseminate policy statements; Association leaders sometimes interpret them in person before a legislative body. Two examples of statements of position illustrating how our society should express its concern in current political action effecting the aged follow:

We stand opposed to the use of the Federal Social Security System as a mechanism for financing a compulsory health-care program. We join organized medicine in stating our belief that the growth of voluntary health-insurance plans is preferable to undue reliance on government for aid. Financial assistance should be available to those who cannot pay for hospital and medical care. The individual has a primary responsibility for his own health and those who can do so should pay their own way. Excessive dependency can be an evil that corrupts character and undermines health.

We support the principle that medical care for aged persons should be available to them in accordance with their needs and the nature of their illness. Physicians who care for elderly people must be free to choose the most appropriate hospital or facility that is available without regard to the nature of the illness, whether psychiatric, medical or surgical. Mental patients are excluded (along with tubercular patients) under certain conditions from benefits of Federal Public Assistance. The Kerr-Mills Bill continued the exclusion. The King-Anderson Bill (HR 4222 and Senate 909) is defective in that it excludes reimbursement in mental and tuberculosis hospitals for the treatment of the elderly. That general hospitals with psychiatric wards might also be denied reimbursement, if the otherwise eligible patient bears a psychiatric label, is also possible. We believe that any health legislation should refrain from excluding the mentally ill from benefits available to those with other forms of illness.

Assumptions and Objectives. On the basis of observed facts, assumptions may be made

that may then serve as objectives in management and in treatment. Comprehensive planning of programs for services to the aged is more effective when based upon objectives thus derived. Table 1 relates objectives to assumptions based upon observable physical changes in the process of aging. Table 2 gives examples of psychological changes with the derived assumptions and objectives. Table 3 does the same for social

factors with relevance to the aging process.

Training in Geriatrics and Gerontology. Training of residents in psychiatry must be broad enough to prepare them to meet the major problems in that specialty. The mental disturbances associated with aging comprise the largest group of *all* psychiatric disorders that require hospital care. The diagnosis, evaluation and treatment of the elderly patient must accordingly be a part

TABLE 1

PHYSICAL FACTORS OBSERVED IN AGING	ASSUMPTIONS	OBJECTIVES
Constitutional differences suggest a biological basis for aging(10)	There is a variability in physiological response and performance capacity	Select as parents the offspring of families who are long lived
Vigor declines through change in the properties of multiplying cells: mutational or epigenetic change	Variability arises from differences in genetic constitution and environmental influences	Awareness of individual differences
Irreplaceable loss occurs in non-multiplying cells: neurons	The organism dies when stress magnitude exceeds his ability to compensate to it(12)	Research in cellular and intracellular structures
Primary changes occur in intracellular substance: collagen(11)		
Perceptual loss	Exclusion of stimuli leads to isolation	Maximize vision, hearing and movement (cataract operations, glasses, hearing aids, dentures, muscle reeducation)
Energy loss	Limits to life exist in terms of energy conversion(13)	Reduce exertion. Rest periods. Graduated exercise. Accept reality of mutual withdrawal and disengagement
	Failing energy curtails social contacts(14)	
Homeostatic balance easily upset	Vulnerability to disorders and diseases increases with age	Periodic medical evaluation Prompt treatment of disease
Occurrence of chronic diseases	Life span is related to the age of onset and progress of the lesions of major diseases(13)	Rehabilitation to overcome disability Older people don't go to the doctor in time, often because they feel their complaints are unimportant (15) Any plan which provides health care should not exclude the mentally ill(16)

of the training of every resident in psychiatry. No man can be considered properly trained in 1962 if he has a blind spot for a third of all hospitalized cases.

Social gerontology is an organized field of knowledge which deals with the behavioral aspects of aging. The multidisciplinary approach of the social sciences adds dimensions to understanding. Special opportuni-

ties for learning in institutes sponsored by universities, or training at the graduate level in two-week courses in geriatric psychiatry and geriatric neurology are desirable. The APA Committee on Aging can do a service to the psychiatrist, interested in reading selectively in the vast literature on the subject, by publishing a reading list at intervals.

TABLE 2

PSYCHOLOGICAL FACTORS OBSERVED IN AGING	ASSUMPTIONS	OBJECTIVES
Reduction of input of stimuli	Rate and variety of interaction will lessen with age(14)	Avoid isolation. Keep in main stream of life Opportunity for freedom of choice and of exercise of control of environment Lights accessible, a radio; supplement resources Constancy—less change A predictable world is less threatening and more secure
Decline in sense of mastery and devalued self image Lessening physical attractiveness and vigor Reduction in speed of response Withdrawal of attention	Ego supporting relationships will defend the faltering ego from attack Resignation from responsibility occurs(14)	Emphasize positive assets and achievements Provide service from same agencies that serve other groups
Bereavement—loss of family and friends by death	Love and approval and the rewards of work, essential to ego strength, tend to disappear	Find a person to be a friend Useful work within limitations Deal with patient in the area in which he can still function
Role change forces disengagement (14)	Change in self perception occurs and loss of responsibility is mourned(17) In the aged egocentricity and egocentricity are more tolerated than in youth When interaction with others is high, deviance is not acceptable (14)	Preserve independence and freedom of action and initiative through support A socially approved role restores self confidence(18)
Reduced adjustment potential with regression and dependency(10)	The strengths and weaknesses of early life determine later life adjustments(10) The narcissistic person is easily insulted and outraged(17) Mental illness is related to psychological stress, loss of self esteem, loss of usefulness and loss of zest for living(19)	Reestablish sense of significance Retain in hospital or long stay annexes only those who need it

TABLE 3

SOCIAL FACTORS OBSERVED IN AGING	ASSUMPTIONS	OBJECTIVES
Cultural attitudes toward aging create stress(20)	Contemporary American social values do not prepare people for successful or even comfortable aging(20) The future oriented, doer types and the cult of youth and beauty as status symbols are favored in American culture that devalues the senior citizen(21) Successful aging is most common in upper socio-economic groups who plan ahead(20) People with inner resources use them in old age(10) Society withdraws from the older person(14)	Enhance prestige of wisdom and experience, character and their person Public attention to successful models of aging
Compulsory retirement	The loss of livelihood and the loss of goal directed activity fosters dependency and regression	Work as long as possible Gradual retirement(22)
Break up of extended family	Older people with daughters make least claim on welfare services(18)	Keep in touch with family and friends
No longer a cohesive economic and social unit with capacity to give adequate care to the aged(18)	Decrease in social life space contributes to isolation and reduced interaction with others and leads to self absorption	Government should support the family and help the old person care for himself, not attempt to supplant the family with state services(18)
One family housing	Disruption of kinship ties tends to diminish responsibility for the aged	Add a room to the home by building an extension for the old person Cultural conditioning to expect family will provide a place for its elderly members
Economic factors	Poverty and malnutrition serve as one source of anxiety for it engenders loss of security. It also results in the inability to attend to medical needs that may extend into mental and physical illness	Planning for old age A central agency for senior citizens A place to turn for help
Housing within means		The elderly should live in own home as long as he is physically and mentally able to do so(18) Housing for elderly that avoids isolation from the community(22)
Subsistence		Social Security and Survivor's Insurance Plans Pension plans Voluntary Health Insurance plans Federal assistance for those who need it and can't pay for it
Hospitalization and medical care		Institutional care only for those who truly cannot be helped to care for themselves and who have no one to assist them

Training of administrators with a special concern for planning health services and systems of management for the senior citizen is also most important. The shortage of persons willing to run a public mental hospital has been so extreme that we have assumed that anyone who occupied the position was an administrator. Tradition bound rationalists often defend themselves and their inadequate institutions from new ideas and from change. The care of the aged has often been dreary fatalistic custody. Trained and inspired leadership is sorely needed. There are few true experts in this great area within the responsibility of psychiatry.

The Positive Role of the Public Mental Hospital. There is an oft repeated stereotype that our public mental hospitals admit thousands of old people who ought not to be there. The physically ill old person, confused, with severe memory impairment and without a family is seen as the one who gets to a mental hospital by default of alternate community resources. It is commonly believed that elderly persons are sent to the mental hospital without any prior attempts to cope with their problems (23).

The majority of the aged are in the mental hospital because they need to be there. Many who are over 60 years old came in when young and grew old in the hospital. With better treatment this group will decrease in number. The elderly presented for admission have severe mental and emotional problems. Hospital treatment is essential for a time. Seldom is the patient able to participate in the planning for his own hospitalization. Families turn for help when they have exhausted themselves in care. Social agencies and general hospitals usually do not seek to send an individual to a mental hospital unless there is an illness, with symptoms that are manifestly disturbing and not responding adequately after a trial of therapy.

Seventy-six percent of persons, over age 65, admitted to a mental hospital were psychotic. Of these, 45% had a previous mental illness requiring hospitalization.⁵ The rea-

son for admissions included extreme excitement with noise and overactivity; combative or threatening behavior. One person in four wandered and exposed himself to danger (see also Vail (24)). Five percent had revolting habits. In only 15% of admissions the presenting complaint was characterized by the simple confusion and memory impairment which figured in the popular stereotype.

Twenty percent had a medical illness and one in four was bedridden or chair bound. Most patients over 65 had families and three-fourths of those admitted lived in a family, although half the time not their own (see also Mohler (25)).⁶ Most of those who lived by themselves had close contact with a family member. Only 6% lived alone in a room, isolated from family and friends.

Many elderly patients had some organic brain damage and some intellectual impairment. Most of these were able to cope with their handicaps and were competent to manage their money. In only a very small percentage did the intellectual deficit extend to interrupt the continuity of experience. They then could not remember what happened yesterday and could not plan for tomorrow. Withdrawal from the main stream of life and from significant relationships occurred. In some this disengagement fostered dissolution and regression that made them dependent upon others. When belligerence is added to resistiveness and when wandering away follows momentary withdrawal of attention, caretakers are less likely, than in cooperative patients, to continue to endure back breaking exhaustion while ostensibly providing total dependent care.

Only one admission in four of persons over 65 referred to the mental hospital represents an emergency. This fact makes feasible an interposed screening mechanism to insure the wisest and most efficient use of community resources for help. Sorely needed in every large city is an agency that can advise people where to get help when they need it. A senior citizens' center can be such a resource to correlate information

⁵ Geriatric Research at the Boston State Hospital is a cooperative project with Boston University Medical School and is supported by the National Institute of Mental Health, Bethesda, Maryland.

⁶ Another survey found approximately two-thirds of the aged who had living children lived apart from them. As age increased, more were likely to live with children or with some relative (26).

on community planning, recreation, education, employment, and health care for all those over 65. The mental health center, the day hospital, the outpatient clinic should all accept elderly patients. The home treatment service can be most helpful in evaluating a patient's need for care and in also offering assistance to the family when there is a group member who cannot or will not come for treatment.

When the mental hospital is chosen, the choice is usually made after a general hospital has determined that it could no longer tie up its beds to provide long-term care. Does admission to the mental hospital help the aged patient? Mental illnesses in old age are serious medical illnesses; about one in three patients admitted is dead within a year. One in three left the hospital within six months for home or a nursing home. (The percentage leaving is of course higher in such groups of elderly as the depressed.) Just under one in three lived on in the hospital for an average of 4.2 years.

These findings suggest that planning of hospital facilities for the aged should provide around-the-clock screening services, resources for intensive medical treatment, prompt psychiatric therapy, progressive care and rehabilitation and long stay annexes designed to promote as much self care as possible.

Flexible admission policies become important when the patient may move through a succession of community facilities. Informal voluntary admissions simplify management. Often, the family will continue to assume responsibility when the patient can be admitted without difficulty for a weekend or a family vacation period. Night care at home may be tolerated if the aged one can spend the day on the hospital ward. Better nursing care, more vigorous medical and psychiatric treatment, extensive resources in rehabilitation to overcome residual handicaps, and buildings designed to meet the special needs of the elderly patient are some of the points for improvement in the public mental hospital that carries the heaviest load in care for those over 65 with a psychiatric illness (27).

SUMMARY

1. Work actively for the adoption of the

major recommendations of the Joint Commission on Mental Illness and Health in your state and at the federal level. It offers to psychiatry the greatest opportunity that will be given in this decade to advance research, training and treatment.

2. Social change is often dependent upon political action. The American Psychiatric Association has an obligation to express itself vigorously in support of social issues with relevance to medicine. We must oppose discrimination against the mentally ill in any local, state or federal legislation.

3. The time is at hand to rethink the national and international responsibilities of the association. To sharpen discussion, I have advocated that the Canadian members be given an opportunity, if they want it, to express their primary allegiance to the Canadian Psychiatric Association. The American Psychiatric Association would then become a national society for United States psychiatrists. If this proposal becomes a reality, I would urge an enlarged function for the Committee on International Relations with active permanent sub-committees in liaison with the Canadian Psychiatric Association and with the psychiatric societies in Central and South America. I would strengthen participation in world affairs through the World Psychiatric Organization and in Pan-American cooperation. As a national society, interested in common problems, the separateness and the nationalism of countries would remain in focus.

4. Psychiatry is in transition. I would encourage movement toward closer relationship with the traditions and practice of medicine. We must first be good physicians. The pursuit of excellence in our specialty of psychiatry is our second major goal. To be worthy of the name of "Psychiatrist" the specialist must be broadly prepared to meet the major problems in his field. In this decade our psychiatric institutions should press toward the acceptable standards of quality practice. We can no longer in conscience excuse second class medicine in public mental hospitals for any cause.

5. The American Psychiatric Association expresses in its constitution the obligation to improve the treatment of patients. In this decade the physiological, psychological and

social problems of aging compel our attention. Already the dominant mental health problem in the United States is old age. From the known facts, we can make assumptions that may lead in turn to formulated objectives. The challenge to psychiatry of un-met needs illuminates some of the major issues presented.

a. Social issues have relevance to medicine. The way one practices and one's ability to achieve a standard of excellence may be determined by legislation. No plan for health care or for public assistance should discriminate against the elderly who are mentally ill. Both Kerr-Mills and the King-Anderson legislation do discriminate against the elderly patients with psychiatric illness.

b. Those over 65 years of age require service for medical disorders from the same agencies, in the same clinics and hospitals that treat younger patients. The diagnosis, evaluation, and treatment of the elderly must be a part of the training of all physicians. No resident in psychiatry can be considered properly trained for the practice of his specialty if he has a blind spot for the management of about a third of all hospitalized mentally ill patients.

c. The public mental hospital has a positive contribution to make to the treatment of the elderly patient. The stereotype of the confused oldster with memory impairment is the exception, not the rule. "Dumping" the aged into mental hospitals actually seldom occurs. The majority of the patients admitted at 65 or over need a period of hospital care, for they have exhausted families and require more specialized medical and psychiatric management than agencies, general hospitals and nursing homes are able to provide. A third of elderly patients admitted are returned to the community. With improved initial management, progressive care and rehabilitation, more may survive and recover sufficiently to leave the hospital and return home.

d. Training in administration has been neglected in psychiatry. The planning of comprehensive programs, of new programs based on new concepts of psychiatric illness, and the translation of

paper plans into effective action programs require able administrators. We must initiate the action to seek out creative and imaginative individuals with a potential for leadership and train them properly.

WALTER E. BARTON
Ninetieth President, 1961-1962

A BIOGRAPHICAL SKETCH

LEO ALEXANDER, M.D.¹

The outstanding contribution which has brought Dr. Barton international renown has been his successful transformation of mental hospital administration into a flexible and imaginative instrument of therapy. While administration at best afforded a challenging opportunity for therapy, its routine and responsibilities were often an impediment. It is probably no accident, however, that the stimulus to use administration itself as an instrument of therapy arose in a state mental hospital, in which the accumulation of treatment-resistant patients provided a challenge much greater in magnitude and numbers than any other single therapeutic task in psychiatry. Against this challenge waves of psychiatric theory have ebbed and flowed and proven weak and ineffective; the state mental hospital may even be called the graveyard of psychiatric theories and methods. It is the immense and ever-supreme proving ground for any psychiatric method, where any theory and endeavor can so easily become outflanked or outnumbered. It is said that when Marshal Foch found himself outflanked or outnumbered, he solved his problem by attacking. Dr. Barton similarly attacked on a broad front—a newly appointed staff, intensive training, and a battery of therapeutic techniques—knowing very well that the problem was too big to be handled by any single method which in less challenging psychiatric situations often sufficed to produce a satisfactory therapeutic result.

Dr. Barton was born on July 29, 1906 in Oak Park, Illinois, the son of Alfred J. and Bertha M. Barton. It may be of interest that the physician attending at his birth was Dr. George Hemingway, father of Ernest.

Dr. Barton's interest in becoming a physician stemmed from childhood; several operations and the long convalescence for a leg broken playing football involved con-

siderable experience with doctors and hospitals and left its mark in the shaping of his ambitions. He graduated from the University of Illinois and went on to the University of Illinois College of Medicine with the intention of specializing in obstetrics and gynecology. But he was particularly fascinated by his electives at the Illinois Psychiatric Institute under the direction of Prof. H. Douglas Singer. Prof. Singer persuaded him to take, as a preliminary for obstetrics and gynecology, one year of psychiatric training in Worcester, at that time a world center. Here Dr. William A. Bryan incited Dr. Barton's lasting interest in administration and trained him. Following eight years at Worcester State Hospital, the last four as senior physician for the men's reception service, Dr. Barton took a year of clinical clerkship in neurology at National Hospital, Queen's Square in London. He then returned to Worcester for four years as assistant superintendent and was acting superintendent for part of that period. In 1941 he published "Family Care, A Community Resource in the Rehabilitation of Mental Patients," advocating community psychiatry and family care before these ideas had become generally accepted within the framework of modern psychiatry. He also published papers in organic fields, most notably syphilis. His educational activities during this period were numerous. In addition to teaching residents, nurses, and students at Worcester State Hospital and belonging to the Faculty of Adult Education at the Worcester YMCA, he lectured at Simmons College School for Social Work, Smith College School for Social Work, and Clark University.

The war helped to push Dr. Barton further in the direction of administration and rehabilitation. He became an army captain in 1942 and was sent first to Walter Reed General Hospital, then made chief of the neuropsychiatric service at Valley

¹ Boston, Mass.

Forge General Hospital. He was promoted to major in March 1943 and organized the occupational therapy department for the army. His paper "The Challenge to Occupational Therapy" was an outgrowth of this work; it advocated useful activities and skills adapted to real work assignments in place of the usual basket-weaving, tie-knitting, and belt-making. As Director of the Army Reconditioning Division he initiated rehabilitation of the deaf and blind and published "A Program for the Care of the Blind in World War II in Army Hospitals." While still a major he was asked to address a convention of the National Women's Clubs of America. His subject was service men returning home, and he followed three long-winded three-star generals on the program. In the ten minutes they left him for his speech he quickly boiled it down to ten simple pointers to remember and sat down. The response was staggering; the address was published under the title "He's Back," and reprints attained a circulation of 250,000. But Major Barton was eager to get overseas and in 1944, as a lieutenant-colonel, went as chief of the neuropsychiatric section of the 126th General Hospital. He left active duty in 1946 and was awarded the Legion of Merit for his wartime achievements.

While still in uniform Dr. Barton returned to civilian practice as Superintendent of Boston State Hospital. Conditions could not have been worse; the hospital had slipped shockingly in the hands of the political appointees of the preceding era. Dr. Barton found the patients reduced to eating with their hands and sleeping between folded mattresses to keep warm. After repeated denial of his request to the Mental Health Department for silverware and blankets, he threatened to set up a public appeal for knives, forks, and spoons in the Park Street subway station: whereupon spoons and blankets were hastily provided from ample army surplus stores. Sanitary conditions at the hospital were scandalous—during Dr. Barton's first summer there were 600 cases of diarrhea and 60 deaths, leading to prompt installation of modern, sanitary kitchen facilities, which have since eliminated this hazard.

During the first five years of the postwar

period Dr. Barton emphasized therapy and training, using his administrative position as a vantage point for the evaluation and intensification of therapeutic measures. His first step was to choose a staff of therapeutically oriented physicians. He found such physicians during the early postwar years, particularly among men interested in a psychodynamic approach to mental illness who were in or had recently completed psychoanalytic training: he looked to such men for unequalled motivation toward new and intensive treatment methods in severe mental illness. Thoughtful organization of the staff, newly comprised of carefully selected key people, established the ward as the unit with the combined efforts of doctor, nurse, and social worker directed toward the patients at a group level. A cabinet of four division heads was appointed, under whom were department heads at the middle level of management. The new emphasis on therapy was carefully grounded on improved diagnostic skills. Training was intensified at all levels. Visiting medical and surgical personnel from a general hospital were added to the staff, thus relieving his psychiatrists whose time had previously been swamped by non-psychiatric details and increasing their psychotherapeutic efficiency by at least 75%. Permanent assignment of medical and surgical residents of a general teaching hospital through rotating periods of six months each at the mental hospital resulted in better psychiatric orientation of these medical and surgical residents, while they in turn improved the medical orientation of the psychiatric staff. Nurses were trained without the usual added demand of duties and services. Thus the medical, surgical and psychotherapeutic capacities of the hospital were all concurrently fortified, as Dr. Barton reported in his paper "Visiting Staff Comes to the Aid of Boston State Hospital" in 1949.

In 1951 when the therapeutic measures of the hospital had attained a firm footing, research projects were begun and eventually comprised at least as much research as at any state hospital in the world. Medical research arose from the new first-rate medical facilities. Group psychotherapy, based on techniques developed in the army, was

introduced and amplified by nurses, social workers, and by occupational and recreational therapists specifically trained in this procedure, which involved the application of elements of psychoanalytic technique to psychotic patients.

Rehabilitation, long a favorite pursuit of Dr. Barton, who at this time was chairman of the American Psychiatric Association Committee of Rehabilitation, was explored, both in the hospital and in the community; Dr. Barton was particularly interested to know whether concentrated rehabilitation efforts could speed the recovery process. The project was financed with federal funds and will culminate in two monographs next year. Selected schizophrenics studied at home were found to respond to the expectations of their immediate families, with the result that those in conjugal families fared markedly better than those in parental families. This was further evidence of the suggestive power of expectation, already a major factor in the open-door policy and further observed in the hospital in the response of patients to heightened environmental expectation, such as the privilege of more attractive and homelike interior decoration in a ward.

Another aspect of research was physical treatment. Insulin and ECT had been the advances—the solid bases for the expectancy situation—which had restored the hope and confidence of therapists, and a battery of treatments had come into wide use: lobotomies were frequent, shock units in the hospital were widespread, there were two insulin units. Until the advent of the new psychotropic drugs, pioneer research was carried out on all these procedures. ECT remains the treatment of choice in selected cases of depression with an intense suicidal drive.

A program of mixed patients which entailed keeping the patient in the same group from the time of admission until discharge was found effective; it provided continuity in therapy by keeping the patient in touch with the same staff throughout his hospital stay and allowed for a balanced patient group with a range of behaviors, giving hopeful expectancy to the less well patient through the presence of the recovering one.

Programs dealing with neurological and

biochemical aspects of the functioning of the central nervous system in organic and mental illness included the multiple sclerosis clinic and a neuraminic acid study.

Twelve research projects are currently in progress. These range from clinical studies on drug usage to training psychiatric aids by group methods. The geriatric research project studied intensively from a medical, psychiatric, social and economic viewpoint patients over 65 years of age. From the study a system of management could be organized to meet the needs of the mentally ill aged. The home treatment research project was begun in 1956, patterned after Querido's work in Holland. A home visit was made by psychiatrist, social worker, or nurse. Family crises were resolved, early treatment started, and in over half the cases admission to the mental hospital avoided.

A "general practice section" associated with the American Academy of General Practice was organized at the hospital in the interest of helping the man in general practice to deal with emotional disorders.

Since the advent of drugs Dr. Barton's efforts have also extended into this area, for example as reported in his paper "The Evaluation of the Effect of Derivatives of Rauwolfia in the Treatment of Schizophrenia."

In 1960 he published *Observations on European Psychiatry*, an important book in broadening therapeutic concepts in this country. His life work will be summarized in his forthcoming book *Administration in Psychiatry*, to be published by Charles C Thomas in June 1962.

Dr. Barton has been associate professor of psychiatry at Boston University School of Medicine since 1952 and in 1960 was lecturer in the department of psychiatry at Tufts University Medical School. Among a distinguished list of administrative posts he has been president of the Massachusetts Psychiatric Association, Massachusetts Society for Research in Psychiatry, Massachusetts Occupational Therapy Association, the Group for Advancement of Psychiatry, and the New England Society of Psychiatry.

Fewest papers besides those already mentioned among the 80 that have come to publication and reflecting a characteristic-

ly broad range of interest and investigation are "Education of the Public; A Function of the Public Psychiatric Hospital," "The Need for Uniform Discharge Statistics in Public Psychiatric Hospitals," "Psychiatric Residency Training in Affiliated Centers," "The Needs of Mental Patients: Expression of Human Needs," "Observations of the Therapeutic Aspects of Administration in Public Mental Hospitals."

Dr. Barton's wife, Elsa Benson Barton, was formerly assistant principal of nurses at Worcester State Hospital; they have three children, John, 28, Gail, 25, and Paul, 15.

In spite of his great role as leader and administrator and his proven mastery of difficult tasks and situations, Dr. Barton's personal manner is surprisingly unassuming, and he is always readily available to confer with and advise colleagues and staff members. By close attention to administrative details and his ever-present availability, he serves both as an example and as a source of support to his staff. His interest in other people and his capacity to understand and know them is immense. In making rounds with him one is impressed with the fact that he knows every patient intimately, even those on the back wards, whose gradual emergence to more responsive living, punctuated by periodic setbacks, he follows with keen and optimistic interest.

A similar spirit of approval and encouragement extends to his staff: he has never to my knowledge reacted negatively to any constructive idea from anyone, and he has welcomed and encouraged the initiative of those under his administrative and professional guidance. This chance to grow and improve themselves has established the men who have trained under him in high demand in other centers; and during a time when many psychiatric hospitals found it difficult to fill their staffs, Dr. Barton has invariably had an abundance of highly qualified applicants. He is even psychotherapeutic in his capacity to overlook or

absorb without trace the hostility of frustrated complainants, thus impressing upon his associates his own tendency to rise above such irritations. His leadership is through example and encouragement rather than exhortation and direction; he concerns himself with the problem at hand rather than the personalities presenting it and is never deterred by apparent obstacles.

In his concepts he is truly eclectic and pragmatic. In the face of conflicting psychiatric theory or dogmatic trends, religious concepts or other philosophic or sociologic views, his composure remains unassailed, and he incorporates them all into his specific mission. In his professional associations he is equally congenial and in harmony with psychoanalysts, clergymen, organicists, and Rotarians. He has never interfered with the basic philosophies of any of his associates. For this reason there has never been any serious conflict between him and his key personnel. He is positive in all his attitudes and avoids negative or defensive stands. He embodies the imperturbability which Osler regarded as a physician's greatest asset.

As one might expect in a man of such immense constructive accomplishments, Walter Barton meets every difficult situation with a natural reserve and a victorious, cheerful and confident attitude. It has been said that he always lives five years ahead of his time, thereby counting anything he sets out to do as already accomplished. This accounts for his indefatigable optimism and unconquerable good humor. While most of us are bogged down in our struggle with the present, he has confidently made the leap ahead to what he intends for the future, in this stage still unadulterated by complicating details and clearly blueprinted in his mind. His faith is with evolution—a firm conviction that just as a phototropic plant grows toward the sunlight, the way of well-intended efforts carefully executed can only be in the direction of progress.

CLINICAL-STATISTICAL ANALYSIS OF POPULATION CHANGES IN NEW YORK STATE MENTAL HOSPITALS SINCE INTRODUCTION OF PSYCHOTROPIC DRUGS¹

HENRY BRILL, M.D., AND ROBERT E. PATTON²

INTRODUCTION—GENERAL DECREASES OF MENTAL HOSPITAL POPULATION

If, in 1955, anyone had dared to predict that the 93,000 mental hospital patients in a state like New York would by 1970 be reduced to between 72,000 and 83,000, the statement would have been rejected as a flight of irresponsible optimism and contrary to all experience. Yet today this statement which appears at the end of our paper is much more likely to be questioned for the opposite reason; to many it will appear as a conservative understatement. This is the fascinating result of the profound and unprecedented change which has been taking place in mental hospital psychiatry generally during the last few years. The causes are open to debate, but the existence of this change is no longer a matter of opinion.

From this country, from Western Europe and from the British Commonwealth have come widespread and consistent reports of slow decreases of patient population, increased rates of turnover, virtual disappearance of disturbed behavior, and extensive liberalization of hospital policies. In the United States the population of the state, city and county mental hospitals has fallen from an all-time high of 558,900 in 1955 to 528,800 6 years later; during the previous half century this figure had risen from 144,098 and had been increasing by 6 to 8 thousand each year up to the year when the trend was reversed(1).

PROBLEMS IN THE INTERPRETATION AND PROJECTION OF THE NEW HOSPITAL STATISTICS

A consciousness of these large changes in mental hospital statistics lies behind much recent psychiatric thinking and colors much planning and yet it must be admitted that

the interpretation of these trends is far from complete and a number of crucial questions still remain to be fully answered. Among them one may list the following:

1. What cause or causes have brought these changes about?
2. What part has been played by the new psychiatric drugs?
3. What are the implications for the future? How far may we project existing trends?
4. What shape should the curve or curves of projection take?

Perhaps the least reliable answer lies in a simple empirical projection of the total recent rate of change, which is after all made up of many relatively independent components. Mental hospital population is not at all homogeneous; there are many kinds of illness and many kinds of patients and they are not necessarily all being affected in the same way. Most of all, we must make some assumptions about the forces behind the changes if we are to interpret them or project them. We must be particularly careful about assumptions regarding future accelerations of the total rate of decrease which on the average now amounts to some 1%-2% per year. The real hope for the future actually must lie in further decreases, but there are dangers in overoptimism since this could lead to premature demobilization of our mental hospital facilities. It would seem important that we examine the data carefully to see how far our hopes for future advance may be based on already established facts.

ANALYSIS OF NEW YORK STATE DATA MAY HAVE GENERAL APPLICATION

The following analysis of the recent experience in the New York State mental hospitals was undertaken with these considerations in mind. Although these data involve only one state, they may have more general application because the changes which have been taking place in New York coincide in

¹ Read at the 117th annual meeting of The American Psychiatric Association, Chicago, Ill., May 8-12, 1961.

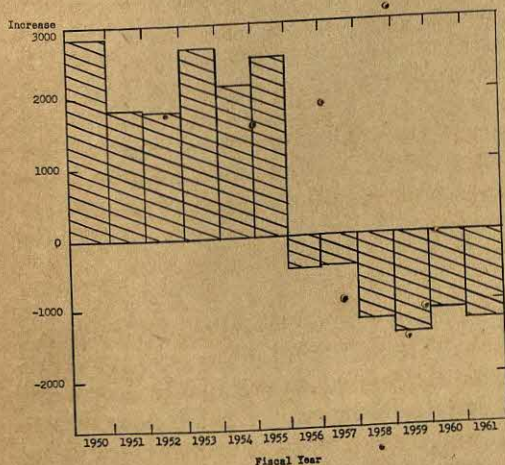

² Respectively, Deputy Commissioner, and Director of Statistics, N. Y. State Dept. of Mental Hygiene.

time with the national and international trend and seem to be of about the same nature, quality and magnitude. They began abruptly in 1956³ and the subsequent population decrease amounts to about 1½ per year.

This paper is based on the total figures for the civil state hospitals of the New York State Department of Mental Hygiene especially for the years 1955-60, inclusive. We will seek (a) to measure the identifiable changes which have occurred, (b) to determine as far as possible how these changes are distributed among the various classes of patients, (c) to examine some of the implications of this pattern of change with regard to the causes which may lie behind them, and (d) to make some estimate of the future developments which appear to be foreshadowed. The emphasis will be on the speed and direction of the existing trends rather than their projection which will be in terms of possible upper and lower limits.

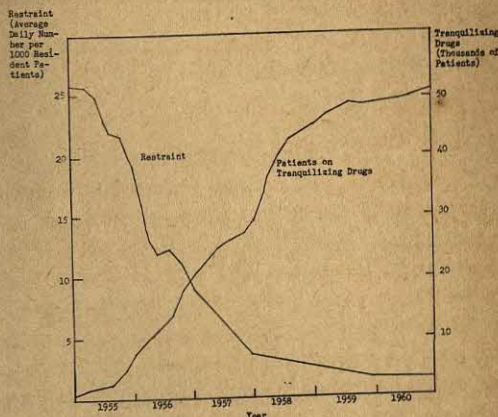

We have already reported(2) on the abrupt change which took place in 1956 coincidentally with the introduction of large-scale therapy with tranquilizing drugs. Population increase was replaced by a decrease (Figure 1), disturbed behavior was sharply reduced (Figure 2), and the atmosphere of the mental hospitals was

FIGURE 1
Annual Increase in Resident Patients

³ Apr. 1, 1955 to Mar. 30, 1956; similarly in this paper all dates are for years ending Mar. 30, unless specified.

FIGURE 2
Patients on Special Therapy and
Restraint-Seclusion Rates

strikingly improved. Our analysis of the data available at that time led us to conclude that the major change in the hospital situation and one to which the improvement could be attributed was the introduction of large-scale therapy with the then new tranquilizing drugs which were given to some 23,000 cases in 1956. It appeared then that a continuation of the overall improvement could be expected in view of the assigned cause. Two years later we reported again on this subject(3) describing a continuation of the same trends with the additional observation that a whole new cycle of favorable administrative changes had taken place and the tempo of improvement had increased. However, the development of chronic cases had been reduced by only 25% to 50% and we concluded that until this was further improved, projections for the future must be limited by this fact. We have now had some 6 years of experience; considerable new data are available and these offer a somewhat more certain base for re-examining our preliminary impressions and tracing further those developments which have been taking place.

A number of the trends have proved to be stable and progressive. Figure 2 shows how the use of psychiatric drugs has steadily increased throughout the entire period and the use of restraint has steadily fallen, although both figures now appear to be approaching a plateau. Clinical opinion is that the control of disturbed behavior has

been stable and even progressive with maintenance of therapy.

A CONTRAST 1950-55 WITH 1955-60

Figure 1 and Table 1 show that the abrupt fall of mental hospital population

measured by decrease of total population.

When we analyse the population changes during the two periods (Table 2) we find that the major population increase in the first 5-year period was 5,111 in the schizophrenic group and in the second period,

TABLE 1
Movement of Resident Patients in New York Civil State Mental Hospitals
Fiscal Years Ending March 31, 1955 through March 31, 1960

FISCAL YEAR ENDED ON MARCH 31	RESIDENT PATIENTS START OF PERIOD	ADMISSIONS	DEATHS	ALL RELEASES ALIVE	ALL RETURNS	RESIDENT PATIENTS END OF PERIOD	CHANGE IN RESIDENT PATIENTS
1955	90,893	21,459	8,078	16,069	5,109	93,314	+2,421
1956	93,314	21,454	8,345	18,862	5,301	92,862	-452
1957	92,862	21,828	8,555	19,785	6,059	92,409	-453
1958	92,409	23,286	9,421	21,732	6,650	91,192	-1,217
1959	91,192	25,254	9,197	25,028	7,561	89,782	-1,410
1960	89,782	26,773	8,996	26,632	7,841	88,768	-1,014

which occurred in 1956 has continued ever since. The contrast between 1955 and 1956 represents a demarcation point between two periods of mental hospital history; up to that time the population trend was upward; since then it has been downward. We can now contrast two 5-year periods (Table 2).

schizophrenia accounted for the major decrease—3,376. Another fact becomes apparent in this analysis, namely, that some of the decrease of the second period was due to the disappearance of paresis which at the present time accounts for a fall of nearly 200 cases each year. This component of the

TABLE 2
Resident Patients and Changes in
Resident Patients by Mental Disorder

YEAR	TOTAL	SCHIZO- PHRENIA	MENTAL DISORDER					GENERAL PARESIS	ALL OTHER
			PSY- CHOSES OF THE SENIUM	INVOLU- TIONAL PSY- CHOSES	MANIC- DEPRES- SIVE PSY- CHOSES	ALCO- HOLIC PSY- CHOSES			
1950	82,971	48,459	11,727	3,526	3,355	2,818	3,455	9,631	
Change from 1950-1955	+10,343	+5,111	+2,843	+879	-152	+875	-287	+1,074	
1955	93,314	53,570	14,570	4,405	3,203	3,693	3,168	10,705	
Change from 1955-1960	-4,546	-3,376	-840	-62	-543	+410	-780	+645	
1960	88,768	50,194	13,730	4,343	2,660	4,103	2,388	11,350	

The first, 1950-55, inclusive, was a span when somatic therapy was limited to electric shock, insulin and psychosurgery. The second, 1955-60, represents a period marked by an introduction of drugs followed by a cycle of administrative improvement and liberalization of hospital policies. This set of figures emphasizes the sharp improvement in results of hospital treatment as

fall will, of course, dwindle and disappear in the foreseeable future—it cannot be projected indefinitely. It is the only component of decrease which now has a clearly defined end point.

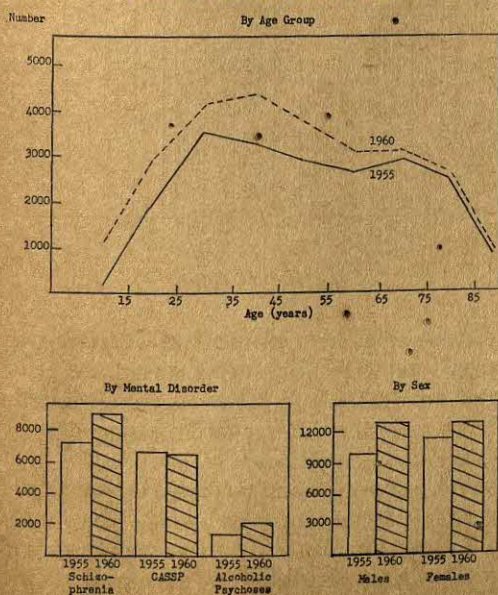

While the number of cases in hospitals has fallen during the last 5 years, the number in aftercare has risen to an equal extent and the total number "on the books" re-

mains the same. The improvement in this total has not been as dramatic as that of the inpatients although a cessation of the growth of population "on the books" is no small achievement.

ADMISSIONS BEGIN TO RISE AFTER START OF POPULATION FALL AND OTHER CHANGES

A sharp rise of admissions followed the fall of resident population, the first significant increase coming in 1958 (Table 1). First admissions rose about 17% between 1955 and 1960, while readmissions increased by almost 50%.⁴ This was due in part to administrative policies which led to discharges of noncertified patients, but it is also probably in part a measure of the newer trend toward easier releases, more rapid turnover and what amounts to more recirculation of certain cases. Even so, the first admissions increased more than twice as rapidly as the general state population, indicating a true increase of use of the mental hospitals. We may now contrast the years 1955 and 1960 in other respects (a) comparing the types of patients admitted, (b) the types of cases released and the rates, and finally, (c) the residual populations. The admissions can be compared in age distribution by two curves (Figure 3), and it will be immediately apparent that two important changes have taken place—

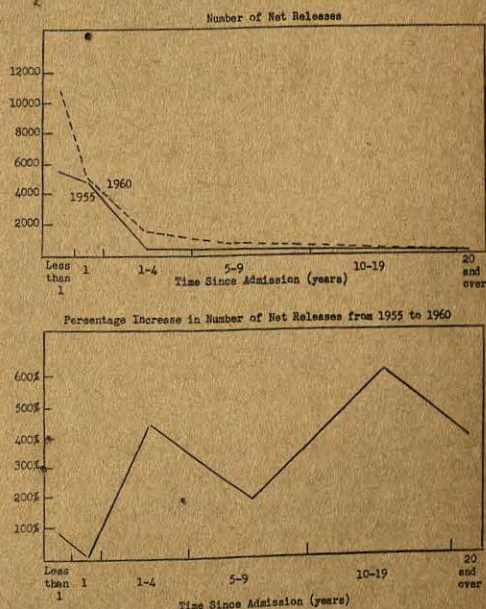

FIGURE 3
Admissions in 1955 and 1960

a sharp increase in admissions at the younger age range, and a leveling off in the upper age group. This rise of younger admissions is of special significance since the outcome of treatment in adolescent cases is less favorable than in patients aged 25-55 and their expectancy of life is very long. Admissions by diagnosis show changes also (Figure 3); particularly there is a slight (148) decrease in admissions for disorders of the senium. This may be immediately related to the increase of nursing home beds in New York State from 31,950 to 42,341 in the period 1955 to 1960.⁴ During this time also, male admissions increased by 30% and female admissions by 20%, while the number of nonwhite increased by 70% and the white by 19%. All these facts are significant because each of these groups has a different outlook under therapy and thus the overall outlook depends on the composition of admissions. Curiously enough, the outlook for release does not vary significantly between first and readmissions in the overall, although there are differences in the various subgroups (Table 6).

When we compare releases (Figure 4),

FIGURE 4
Net Releases Alive in 1955 and 1960
by Duration of Stay

⁴ It is perhaps noteworthy that this 11,000 increase did not have a greater impact on geriatric admissions.

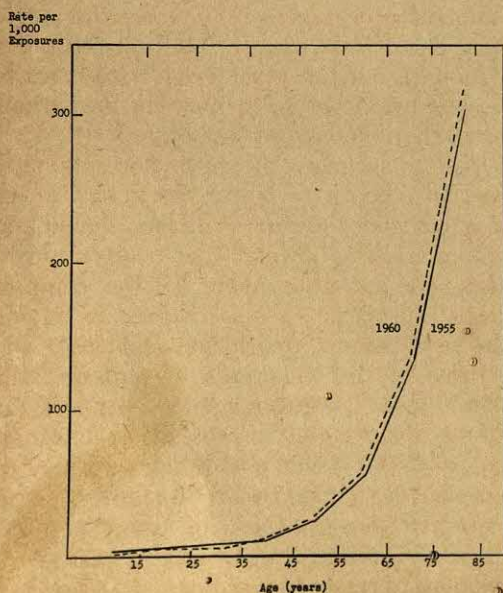

we find that in the last 5 years this component too has changed, not only in size, but also in shape. A release profile by duration shows that releases have increased particularly in the newly admitted groups and that the gain in the gross number of released cases is greatest in new cases, while the greatest proportional gains are in the cases of longer hospital stay.

DEATH RATES STABLE, NUMBERS INCREASE

Deaths have also increased in the last 5 years (Table 1). This is directly related to the fact that the median age of the hospital patients has risen from 54.9 to 56.9 years and, in turn, this is the result of a differential increase in the releases of younger patients with a selection of older cases for retention (Figure 7) and also is related to an increased life expectancy of the long term chronic cases. In this period the average age of schizophrenic patients dying in the hospitals has increased from 63.7 to 65.3, while the average time in hospital for these patients has gone from 23.0 to 25.0 years.

The profile of death rates by age group shows that there is no significant change of rate at any age (Figure 5). The increase in number of deaths is due almost entirely

FIGURE 5
Age Specific Death Rates in 1955 and 1960

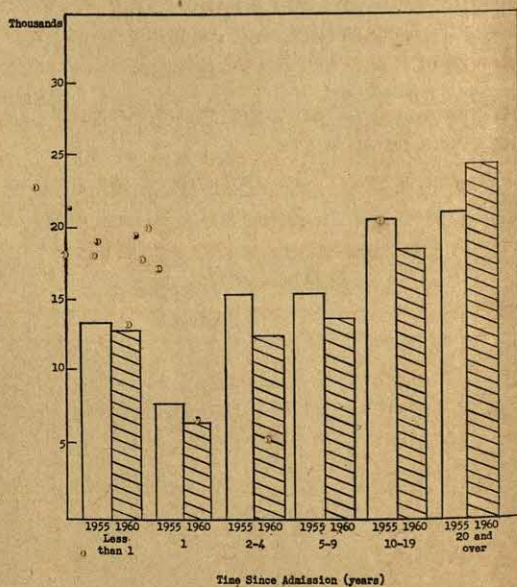

to an increase in the number of older persons in the hospitals.

The stability of death rates, especially in the younger age groups, offers a measure of certainty that no significant long term toxicity will ever be identified in the use of the new drugs. Large numbers of patients have been on such drugs for long periods, nevertheless, age-specific death rates have not risen and clinically no such toxicity has appeared.

ANALYSIS OF RESIDUAL POPULATION

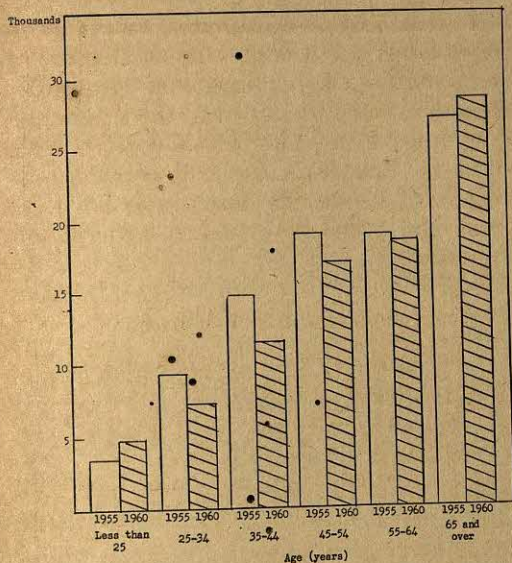

When we come to the changes in the residual population we find some of our sharpest and perhaps some of our most important contrasts. A population profile comparing the residual population of 1960 with that of 1955 (Figures 6, 7, and 8) shows

FIGURE 6
Resident Patients in 1955 and 1960
by Duration of Stay

that there has been a decrease in all groups except the very long term cases admitted prior to 1940, long before active somatic therapy was freely available, especially for maintenance. Furthermore, it is noted that the diagnostic group of schizophrenia showed the most marked fall (Figure 8). In this group (Figure 9) the youngest and oldest age groups showed increases, while

FIGURE 7
Resident Patients in 1955 and 1960 by Age

the middle groups showed decreases. The increase in the oldest group of all diagnoses (Figure 7) was due to the aging of long term schizophrenics, not an increase in psychoses of the senium (Figure 8).

THE PROBLEM OF CHRONICITY—A 5-YEAR MEASURE OF RESULTS

In many ways the problem of the mental

FIGURE 8
Resident Patients in 1955 and 1960
by Mental Disorder

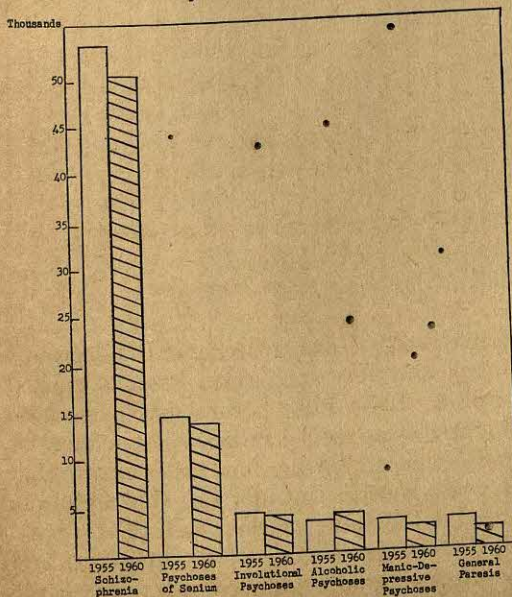

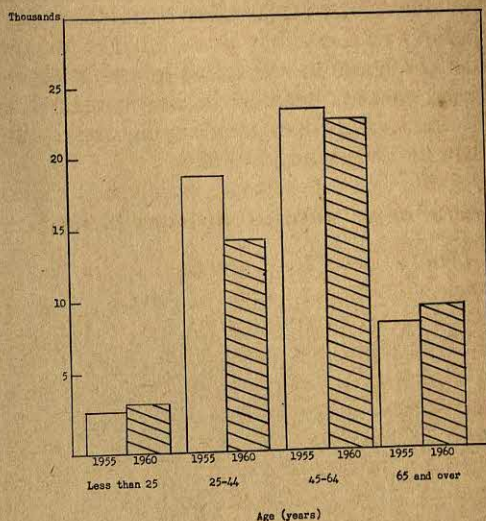

FIGURE 9
Resident Patients with Schizophrenia
in 1955 and 1960 by Age

hospital resolves itself into the problem of chronicity. After the rapid turnover of the earlier cases, the increased admissions, releases, returns and readmissions, what is the final result?

This has been the substance of many questions raised repeatedly, especially by those who have had long experience with mental hospitals. Are we really getting better results than we have ever done before or are we seeing only some statistical juggling? Are we inflating the figures by the admission of less serious cases for brief periods of time, merely diluting the older data with much new material, but yet really accomplishing nothing more for the serious cases than we have done before?

Just as surgeons measure cancer therapy results in terms of 5-year cases, so also we may consider the cases who have failed and who are in the hospital 5 years after admission. We can thus avoid all the complex statistical manipulations involved in tracing the admissions, treatments, releases, and returns of the thousands of patients who flow annually through our hospitals. In doing this we must make sure that we are not misled by the possibility that the increase from 21,000 to 26,000 admissions per year has been the result of admitting 5,000 cases of a milder type. For this reason, we propose to relate the number of 5-year cases

not to admissions, which have fluctuated so markedly, but to the base population of the state.

We can ask several questions in this connection :

1. How many 5-year cases are now accumulating annually in the hospitals ?

2. How does this number compare with the number added in 1955 ?

3. What is the *rate* at which such cases have been produced each year ? Is this rate rising or falling ?

4. The future fate of these 5-year cases is largely measured in terms of expectancy of life in hospital since releases play only a very small role in their outcome. What estimate can we make of the future size of the chronic population of the mental hospitals from a series of such cohorts ?

5. Finally, since data as to duration of hospital stay are now compiled annually, what can we observe in scanning a table in which all such data are gathered in one place ?

During the fiscal year 1955, 4,385 cases completed the fourth and entered the fifth year of hospital life (Table 3). They were the residual of 21,466 cases admitted during 1951. In 1960, the number who had shown the same degree of failure was 3,435 and they were the residual of 21,454 individuals admitted in 1956. Expressed in rates per 100,000 of the corresponding population of the state, we find that the 5-year chronicity rate fell from 27.9 per 100,000 in 1950 to 20.5 in 1955. Table 3 also shows the effect on age and diagnosis. Particularly to be noted is the rise in median age of this long term group from 51.9 to 56.5 due to improvement of treatment results between ages 25 and 54. It is also noteworthy that of the decrease of 950 in total 5-year cases, schizophrenia accounted for 672 (Table 5) although chronicity has been reduced to some degree in all types of diagnoses listed. So far we have clear evidence that the second cohort of cases exposed to the newer therapies throughout all of their hospital

Fiscal Year of Admission indicated by subscript.

lives have shown a sharp reduction of chronicity. This amounted to an overall 22% compared with a similar group admitted 5 years before and not exposed to such treatments nor to the administrative changes which have also occurred. Since the state population rose during that time, the rate of chronicity per 100,000 population has fallen somewhat more (25%).

If the stream which has been feeding the pool of chronic cases has been diminished by 22%, we may logically project from this a final reduction of the chronic group by 22% providing death rates for chronic cases remain stable. Actually the slow increase of the age of chronic cases (Figure 7) tends to increase the number of deaths (Figure 5) although improved medical treatment methods promise to decrease rates of death in the future.

The current estimate of 22% falls at the lower end of the prediction made in our second report(3) "chronicity has been reduced by 25% to 50%." This statistical conclusion confirms common clinical experience that a significant number of psychiatric patients are refractory to any existing method of treatment, and we know of no technique that claims freedom from chronic outcome.

THE QUESTION OF FUTURE ACCELERATION OF POPULATION DECREASE

Is 22% a relatively static rate or is there reason to believe that subsequent cohorts admitted after 1956, when drug therapy and administrative changes were better developed, have fared better than did the 1955 group which presumably had less adequate treatment early in their hospital lives? If we examine the tables for each of the years since 1955, we do indeed find some evidence of a progressive improvement (Table 4). The 5-year group has fallen irregularly from 3,972 to 3,185, while the 4-year group has dropped from 4,385 to 3,435. The 3-year group has a similar story with a fall from 4,734 to 4,023. The 2-year group, from which each of the others will be fed, shows improvement each year, although here we seem to be reaching a plateau. The successive drops amount to -242, -514, -321, -137, and -20. In the 1-year cases we see something of the same pattern with a fall of -677, -375, -123, then a -7, -154. The cases under one year reflect the current year's admissions too closely to warrant interpretation in this connection, though it is interesting to note that the residual at the end of each year of treatment

remains much more constant than does the number admitted during the year.

Here we find indications that further decreases in the 5-year case group may be expected for several years to come but that this improvement may be moving toward a plateau. The table also seems to imply that a plateau has already been reached with respect to the cases of less than 1-year duration and is perhaps being approached by the next two classes.

How far may we expect the chronic cases to be decreased and what characteristics do they present which set them off from more fortunate ones? We were not in a position to provide a full answer to this question, but in connection with a cohort study it was determined that no less than 3,045 of the 3,652 patients who remained in hospital from the 1955 group of admissions had never had a single placement on leave, convalescent care, or family care, or escape for 4 years. It becomes apparent that these represent a hard core of cases in which reasons against release were operating continuously during their hospital residence. Schizophrenia accounted for a third of the total psychoses of the senium somewhat more, and the rest were made up of a scattering of other diagnostic categories. A sampling indicated that they were almost universally without effective family ties. It was noted

that male schizophrenics aged 45 to 64 did most poorly.

CHRONICITY IN SCHIZOPHRENIA REDUCED—NOT ABOLISHED

Since so much chronicity is bound up with the question of schizophrenia, it is important to review the changes which have taken place in this category; the one, incidentally, which has benefited beyond all others from the recent developments. Here we find reflected the changes already described in relation to the total group of chronic cases. The greatest reduction in schizophrenia has occurred in the 2-, 3-, and 4-year figures (Table 5). The fall of 4-year cases (those entering the fifth year) amounts at this time to about 33%. Since it is through this group that the very long term cases must come, this reduction of the size of the stream will eventually reduce the residual pool of schizophrenics, which as yet has shown no significant change although within the group one finds (Figures 9 and 10) that this is due to the accumulation of old cases admitted 20 and more years ago.

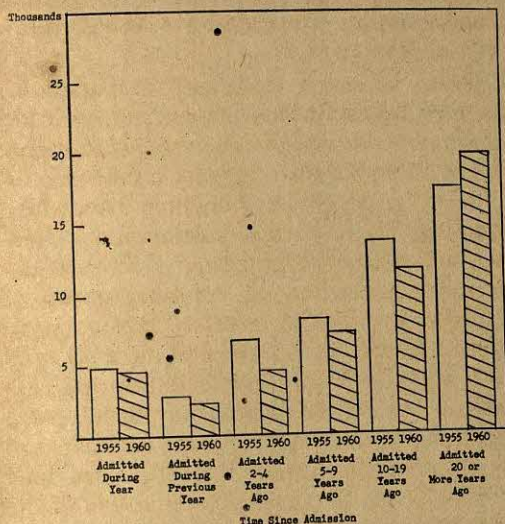

COHORT STUDIES

A useful method of analyzing population movement is the cohort study. Since this means following each year's admissions

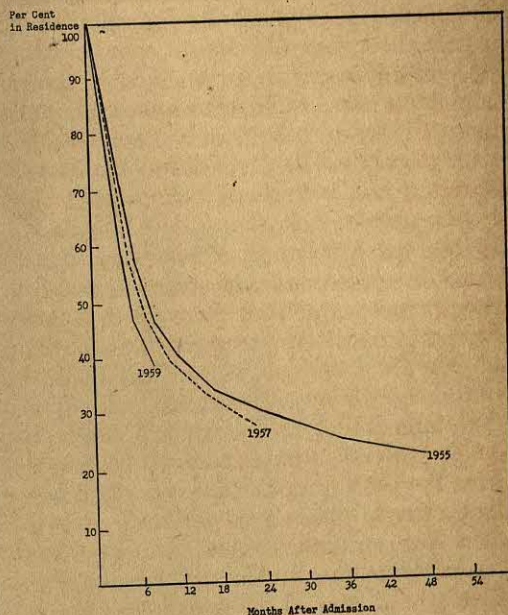

FIGURE 10
Resident Patients with Schizophrenia in
1955 and 1960 by Duration of Stay

throughout their stay in the hospital, it has two drawbacks: first, it is slow in producing results; second, it does not permit contrasting the response to change of environment or therapy because the cohorts overlap in time. The cohorts to be described in this section have been followed since 1955 but they give us no way of contrasting the effect of new treatment and administrative techniques with preceding conditions since each of the cohorts was exposed to the newer methods as they were developed. Nevertheless, each successive group after 1955 had increased exposure to the new methods and if there has been an improvement from year to year, it should be measurable. If there is any factor of acceleration of population fall, this particularly should be visible. Perhaps more important is the fact that the cohort figures will give direct evidence about the stability of releases. False impressions created by rapid release and return of patients will be corrected by these curves which measure the ability of patients to remain out of hospital.

Figure 11 (all ages, patients in residence by fiscal year of admission) shows the trend for steady improvement year by year with the spread between 1955 and 1959 amounting to some 7% at the one-year point when 34% of the 1959 cases remained in hospitals as contrasted with about 40% of the 1955 cases. It is interesting to note that the im-

FIGURE 11
Per Cent of Patients Admitted in 1955, 1957, and 1959
in Residence by Time After Admission

provement in 1956, the first year of drug therapy, was further increased in successive cohorts. There is some indication that the spread between curves will tend to diminish in the course of time (unpublished data).

Taking the age group 25 to 34, which is probably the most favorable for therapy, we find that the differences are considerably greater. Between 1955 and 1959 the number of cases remaining in hospital at the 6-month point had fallen from 56% to 36%, with some progress in each of the 4 successive cohorts (unpublished data), implying a progressive improvement of results in newly admitted cases. Here also the spread between the curves tends to diminish in the course of time. It should also be pointed out that the cohort method, based on percentages of residual patients, does not correct for dilution due to increased admissions, but this factor is not important in 1956 or 1957. It was not till 1958 that admissions began to rise (Table 1).

STABILITY OF RELEASES AT ABOUT PREVIOUS LEVEL

Perhaps one of the most persistent questions which has been asked since patients began to be released in larger numbers and

population of mental hospitals began to be reduced was, "How long will these improvements last?" The immediate stability has now been well established; the number of

patients returning from convalescent care has not risen disproportionately to the releases (Tables 6 and 7).

However, long term stability is still diffi-

cult to assess since we are now in only the fifth year of follow-up of the large increase of released cases. The easiest measure of such late returns is in readmissions although this can be quite misleading. Particularly, calculations should allow for the fact that as releases increase, the population at risk rises and this alone will increase the total returns even if the risk of return per patient remains the same. To evaluate this factor fully, one would also have to determine whether the readmission is brief or long term and whether these cases have become intractable and no better off than if they had not left the hospital in the first place. While we have relatively little direct information on this whole subject, we do have data bearing on it and it all converges to the same general principle.

FAVORABLE OUTCOME IS ASSOCIATED WITH EARLY RELEASE—CAUSE OR EFFECT ?

There is a positive association between early release and final outcome and we have already described the strong relation between final chronicity and hospital stay without a release. Those cases which are released soonest (Figure 12) tend to have

FIGURE 12
Per Cent of Patients Released on Convalescent Care in 1955-1957 Who Were Back in Hospitals by Length of Time Between Admission and Release

the smallest rates of return, and this appears to include even alcoholics about whom it has long been said that the longer they remain

in hospital, the better is their prognosis for complete remission. Are these statistics favorable because the best cases are selected for early release or because there is a therapeutic value in early release? Perhaps both factors are operative. One could easily find clinical support for either point of view. However, the figures clearly show that any treatment evaluation study which does not fully control for the releases during the first few weeks of hospital life is strongly biased by this omission. Comparing total treated cases with total untreated cases may unwittingly include the best cases among those who got no treatment because they recovered too quickly. In our data it appears that a considerable number are released within the first few weeks after admission and measured by their rate of return, these are also the best cases. For some individuals it may be true that quick release spells quick relapse, but for the group, the cases released quickly have the least amount of relapse. It may also be said that perhaps society retains best those whom it accepts back most readily.

Figure 12 is clear-cut with respect to this question. Cases released in the first 3 months of hospital life have less than 10% likelihood of being back in the hospital at the end of a year and even this statistic improves slightly in each of the next 2 years. Patients released after 19 months of hospital stay have a 25% chance of being in hospital at the end of the year and this figure rises somewhat in each of the next 2 years. In Figure 12 prognosis for successful release is inversely related to duration of hospital stay.

What is perhaps most striking is that this holds good for alcoholics also. Only 9.4% of those released within the first 3 months were back in the hospital at the end of the year; with 4 to 6 months of hospital stay, the relapse rate was 19.3% and this increased by regular steps to 32.7% for those released after 19 months of hospital stay. When followed for 2 years, the figures were better for each group, namely, 8.3%, 13.8%, and 27.5%, respectively, and by the third year, the figures were 6.9%, 9.6%, and 25.7%.

We may ask, is there any indication that prognosis deteriorates with readmission? The information available to us at this time

is to the effect that first admissions have a release expectancy somewhat higher than do readmissions in the younger age groups, but the difference is not large if we allow for the fact that presumably the more difficult cases are the ones who return. Table 6, for example, shows that 76% of first admissions aged 25 to 34 were out at the end of 12 months, while the corresponding figure for readmissions was 67%. In older cases the relationship is reversed and readmissions have a greater release expectancy than first admissions, but this is probably due to complicating death rates which play an important role here.

**RECIRCULATION OF CASES NOT EXCESSIVE—
ECONOMIC FACTORS—COMMUNITY MENTAL
HEALTH SERVICES**

One question may be answered quickly—Are we dealing merely with a more rapid *recirculation* of cases, beneficial though this may be? The answer appears to be “no.” Releases have increased by over 10,000 and admissions by 5,000; the difference accounts essentially for the population decrease (Table 1), and shows clearly that there has been a net gain in discharges and not merely recirculation. Among other facts established with regard to stability in the past few years is that the improvement of hospital figures is less vulnerable to economic factors than was originally feared. In the economic recessions of 1958 and 1960 we identified no influence on returns to hospital.

Finally, we may point out that outpatient services have not as yet had any visible influence on mental hospital psychiatry as it has been developing in New York State. The organization for community mental health services began functioning in 1955. By 1959 there were 46,000 admissions to the psychiatric divisions of general hospitals and 68,000 admissions to outpatient psychiatric clinics in New York State. These had developed during a period of increasing admissions to mental hospitals but we do not believe that the rise was related to the community program. The increases have occurred both in areas of the state where clinics and psychiatric beds in general hospitals exist and in other areas where such facilities are lacking or little developed.

Also, it should be noted that the rise of admissions is a world-wide experience and not limited to areas with community mental health services. So far, it seems that a saturation point has not been reached for either inpatient or outpatient admissions. However, the limit of need for hospital beds has been reached and is now falling. The main inpatient issues which remain to be settled are the patterns of organization and distribution of services. For outpatient services, all limits remain to be determined.

CONCLUSIONS

1. Fall of population in the New York State mental hospitals has continued through its sixth year. The rate of overall decrease has been about 1½% per year. Several elements in the total population can be identified as most affected by the change and with the exceptions of paresis and psychoses of the senium noted above, the decreases mostly involve those groups where drug therapy has the greatest clinical advantage over previous methods, this effect subsequently having been intensified by stepped-up total programs.

- (a) In general, the decrease is most marked in the younger age groups and in the 2- and 3-year cases and there is an actual increase of the very long term older cases (Figures 6 and 7). Releases have risen in cases of all durations of hospital life (Figure 4).

- (b) The 5-year fall (1955-60) of schizophrenic cases is the most impressive of all diagnostic groups and amounted to 3,376. This began abruptly after the introduction of large-scale drug therapy in January 1955 and has continued ever since. In this same period (1955-60) there was a marked increase of 2,064 in schizophrenic admissions. Within the schizophrenic group, the decrease was most marked in the 1- to 4-year cases (Figure 10) and the age group 24-44.

- (c) In sharp contrast, the number of resident cases of alcoholic psychosis has actually risen (Figure 8).

- (d) There has been a diminution of cases of other functional psychoses although of less significance than that seen in schizophrenia (Figure 8).

2. The relationship of the foregoing changes to the introduction of large-scale

drug therapy remains no less open to debate than it was in May 1957 when we outlined our reasons for seeing a positive relation. We still find no other explanation for a change of such magnitude which has involved hospitals across the country and abroad and which, in its larger aspects, began quite abruptly in 1956, the year when psychiatric drug therapy first began to be applied on a large scale. There is no doubt that population reduction may be and has been brought about by many other means. However, the fact is that it was never before accomplished on a scale remotely approaching the national and international level reported since 1956.

3. However, the question as to the significance of drug therapy in this entire situation has taken on another meaning and implication. For the first few years the issue which seemed to hang in the balance was whether drug therapy should really be accepted and come into general use. It now seems that further debate on this point has lost its significance because regardless of the formal opinions which may be expressed, the fact is that hospitals throughout the world are using this method. It appears from various communications that practice varies much less than theory and that the established norm probably runs at about 60% of the population of the various mental hospitals; at least this is the impression which one gets from informal communications.

The question of drug use thus seems to be settled in a practical sense but the original problem retains its importance because insofar as the mental hospital improvements are due to drug therapy, they may be limited by the limitations of drug therapy, both as to the proportion of cases relieved and the pattern of individual improvement and its conditions. If, for example, release is due in a significant degree to such therapy, drugs may have to be maintained indefinitely afterward. In practice this is gradually being accepted and here, as often occurs, practice seems to precede theory since many psychiatrists are still dubious about this entire subject.

4. If drugs play a large role, we shall have to accept another limitation. Up to the present time they have proved much more

effective in reducing active positive symptoms than in controlling negative ones, such as occupational inertia, vocational incapacity, and lack of initiative for constructive occupation—long a prime problem in the care and treatment of the mentally ill. Much effort will have to be expended in social and vocational rehabilitation, but perhaps we have not given due recognition to the fact that defects in this area are not an accidental and secondary problem but a primary and central one directly related to mental illness and especially schizophrenia, and it may be expected to become more prominent because of the differential effect of drugs on mental symptoms.

5. Perhaps most important of all is the recognition of the fact that striking and valuable as the recent improvements in hospital results have been, it is also possible to exaggerate them. The recent decreases of hospital population have continued at the rate of 1%-1½% per year in our state, and careful review of the data indicates that this rate may be expected to continue. There are some indications that a degree of acceleration will take place in the next few years to be followed by a possible plateau formation in the course of time, but chronic cases are still accumulating in our hospitals in numbers only 22% below those which had filled some 53,000 beds with long term cases in New York by 1955. In 5 years the rate has fallen from 27 per year per 100,000 of the state population to 20 per year and the mean age of such cases has risen from 50 to 56 years (Table 3). All this has implications for future decrease of the number of long term mental hospital beds which will be needed. However, the number of beds required for short term cases (less than one year) has apparently reached a plateau at about 12,000, and there is also some indication that the number of beds for intermediate care (1-4 years) will reach a plateau at about 16,000 beds, and the fall of chronicity rate is to some extent being counterbalanced by increase of state population.

6. Table 9 gives our projection of the resident patient population of the New York State mental hospitals in 1970. We believe, as a matter of judgment on the basis of the evidence given above, that in the 10 years

from 1960 to 1970 there will be a continued reduction which will leave a mental hospital population of between 72,000 and 83,000

resident patients. This would be a reduction amounting to between 6% and 19%. We believe this to be a reasonable degree of

TABLE 8

precision for program planning.

7. Finally, statistical evidence is lacking for a massive acceleration of the process of shrinkage. Much of the limitation appears to be inherent in the drug therapy with which the process was begun. Any advance beyond the present rate seems to require either a newer and better technology or a newer administrative and organizational approach and it is to be hoped that no type

of innovation will be applied on a large scale without provision for critical and adequate evaluation.

AN APPROACH TO THE EFFECT OF ATARAXIC DRUGS ON HOSPITAL RELEASE RATES¹

LEON J. EPSTEIN, M.D., RICHARD D. MORGAN, A.B., AND
LYNN REYNOLDS, M.A.²

The Department of Mental Hygiene has for the past three years been assembling its routinely collected data for the purpose of cohort follow-up analysis as outlined by Kramer(1), Israel and Johnson(2), and Pollack(3).

Mental hospital population studies have, until recently, been limited to census-type approaches or cross-sectional views. With such approaches one could ascertain for any given period the number of admissions, discharges or deaths, or the patient population at any given time. The advantage of cohort follow-up analysis is that it permits one to obtain such measures as the likelihood of release as well as estimates of length of hospitalization prior to release for certain cohorts of patients. The term *cohort* is applied to any group of patients with one or more characteristics in common, such as age, sex, race, etc. An example of the information which one may obtain from such cohort follow-up analyses may be seen in Figure 1.

This chart describes the status as to hospitalization of all white male schizophrenic patients 25-44 years of age who were admitted to California state hospitals for the mentally ill in 1949. At any point after admission one is able to determine the percentage in each category, and trends are readily recognized. It is apparent that this technique has wide usage in studying trends with respect to certain characteristics of patients under treatment as well as certain aspects of the character and outcome of their treatment. It thus provides an additional important tool not only for operational research but supplies base lines for continuing reviews of the nature and effect of treatment programs.

One of the initial problems approached

with the aid of certain of these cohort data was the impact of tranquilizing drugs on the recent steady decline in state mental hospital populations. This decline is a phenomenon which has been occurring in California as well as in many other states (4). This report is the first of a planned series wherein the use of drugs with various patient cohorts will be studied. The data for these studies consist of information concerning drug usage in the State of California Dept. of Mental Hygiene. For a period of 30 months, extending from July 1, 1955 to December 31, 1957 information was recorded for every patient in the 10 mental hospitals to whom such drugs were administered: age, sex, diagnosis, legal classification (method of admission), name of drug, number of days on drug, total amount of drug, date initiated—date ended, and reason for discontinuing.

During this period some 20,000 courses of drug therapy were carried out on some 10,000 patients. This hospital population sample is now in the process of being studied and interhospital comparisons of drug usage are also being made. The only limitations on drug treatment in all hospitals were budgetary, i.e., in terms of funds available for psychotropic drugs. The drug allotment per patient, however, was the same for each hospital. For the first year of data collection, this limitation is important since, at the beginning, the California Dept. of Mental Hygiene's expenditures for these drugs tended to be comparatively low.

It is not possible at the present time to describe the drug-treated group as a whole, since the 20,000 IBM cards relating to this group are still interfiled with the total deck of some 300,000 cohort cards pending the completion of certain cohort studies. It is possible, however, at this stage to present certain data relative to white male first admissions between the ages of 25-44 with the diagnosis of schizophrenic reaction. We are endeavoring to see, by looking at sig-

nificant population sub-groups such as this one, what conclusions we may be able to draw about the relationship between length of hospitalization and drug treatment. We also plan to examine more closely those

patients whose hospital stay appears to have been altered because of drug treatment in situations where these drugs are used in routine fashion in our settings. In addition, we are endeavoring to elaborate further this

method for the study of problems associated with patient movements to and from institutional settings.

One is painfully aware, to be sure, of the make-up of drug data such as those being studied here. They involve a variety of physicians, of hospital settings, of drugs, of drug timing, drug dosage, of length of treatment and of discharge criteria. In short, there are no experimental controls with respect to usage, and the data represent information about tranquilizing drugs as they were used in this given period in all of California's state mental hospitals. As such, however, they are excellent for studying drug effects and release rates under operational conditions. To be sure, release from a hospital, in and of itself, leaves much to be desired as a sole criterion of the effec-

tiveness of any form of treatment. The question at hand, however, is that of the relationship between ataraxic drug usage and release rates.

Two groups of first admission male schizophrenic patients are being studied: those admitted in the 1956 and 1957 fiscal years to the 9 major state hospitals for the mentally ill. For fiscal 1957, 740 such patients were admitted and for the previous year, 673. Figures 2 and 3 illustrate the hospital retention rates of these patients at given points in time. Separate curves are given for those patients treated and those not treated in each of these years.

Certain factors become apparent on inspecting these figures. Of 740 cases in the 1957 group, 356 cases, or 48%, received ataraxic drugs at some time during their

FIGURE 6

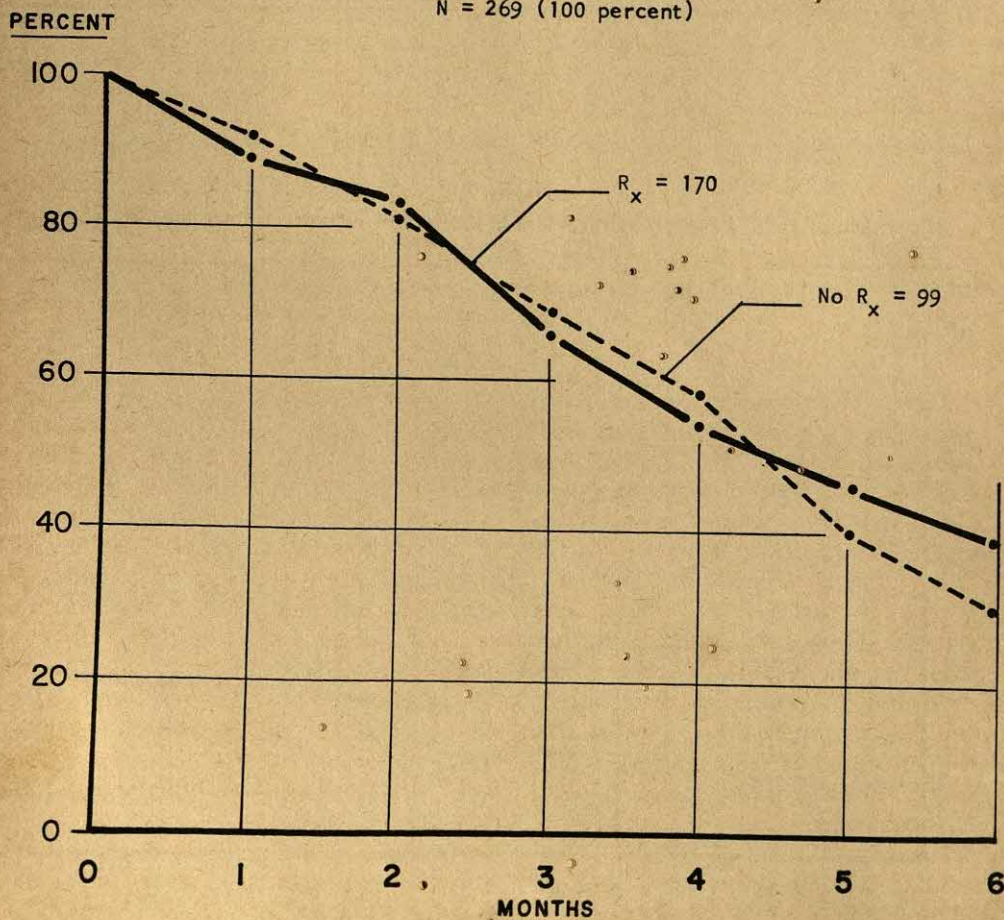

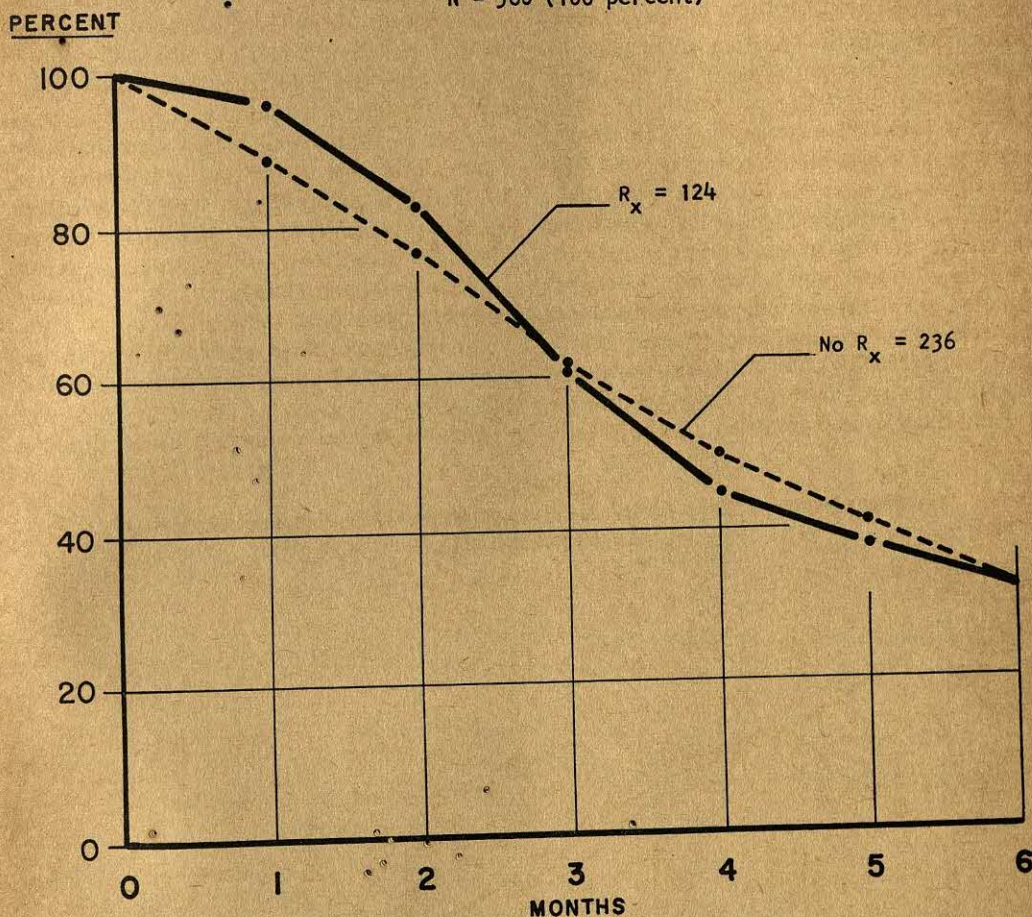

FIGURE 7
The Retention Rates of Drug Treated and Non-Drug Treated Patients in Three Hospitals of
Low Drug Usage—1957

N = 360 (100 percent)

first 6 months of hospitalization. As we know, the release rate of this group tends to be comparatively high during the first months of hospitalization. Seventy-one percent of the non-drug treated and 64% of the drug treated groups had been released within 6 months of admission. The same trend is evident for the 1956 population under study. Thirty-six percent of this group received medication at some time during the first 18 months of their hospitalization; 67% of the non-drug treated patients were released at 6 months; and 88% at 18 months. For the drug treated patients, 63% had been released at 6 months and 74% at 18 months.

These data are amenable to a host of interpretations. It is apparent that if one

looks only at these data one is able with self-righteous courage to form a conclusion as to their meaning which is quite in keeping with one's presently existing philosophy about the effectiveness of drugs. Thus, one might say, these data indicate that in California patients were kept on maintenance rather than treatment dosage. Another might say, they clearly indicated that staff physicians were carefully selecting only the sicker "patients who otherwise might have stayed even longer. Another might go so far as to say the reason for such curves is that the treated patients remained hospitalized largely because of side effects and might have been able to leave the hospital, were the treatment terminated. We are sure that there are not only other interpretations

but that most readers believe they could predict the specific interpretation which would be offered by many of their colleagues.

The attempt was made, however, to carry this one step further at this early stage of deliberation. Comparisons were made between those 3 of the 10 California state hospitals for the mentally ill which treated the largest proportion of their patients with ataraxic drugs and the 3 which treated the smallest proportion. One small hospital was not considered because its population consisted largely of non-psychotic sexual offenders and thus would provide scarcely any data for study. The Department's teaching and research center was also excluded because of its small caseload of schizophrenic inpatient admissions.

Figures 4 and 5 present for 1956 the retention rates of first admission male schizophrenic patients in the 3 high and 3 low drug usage hospitals. In the high drug usage hospitals, 49% of the patients were drug treated during their first 18 months of hospitalization as opposed to 26% in the low drug usage hospitals.

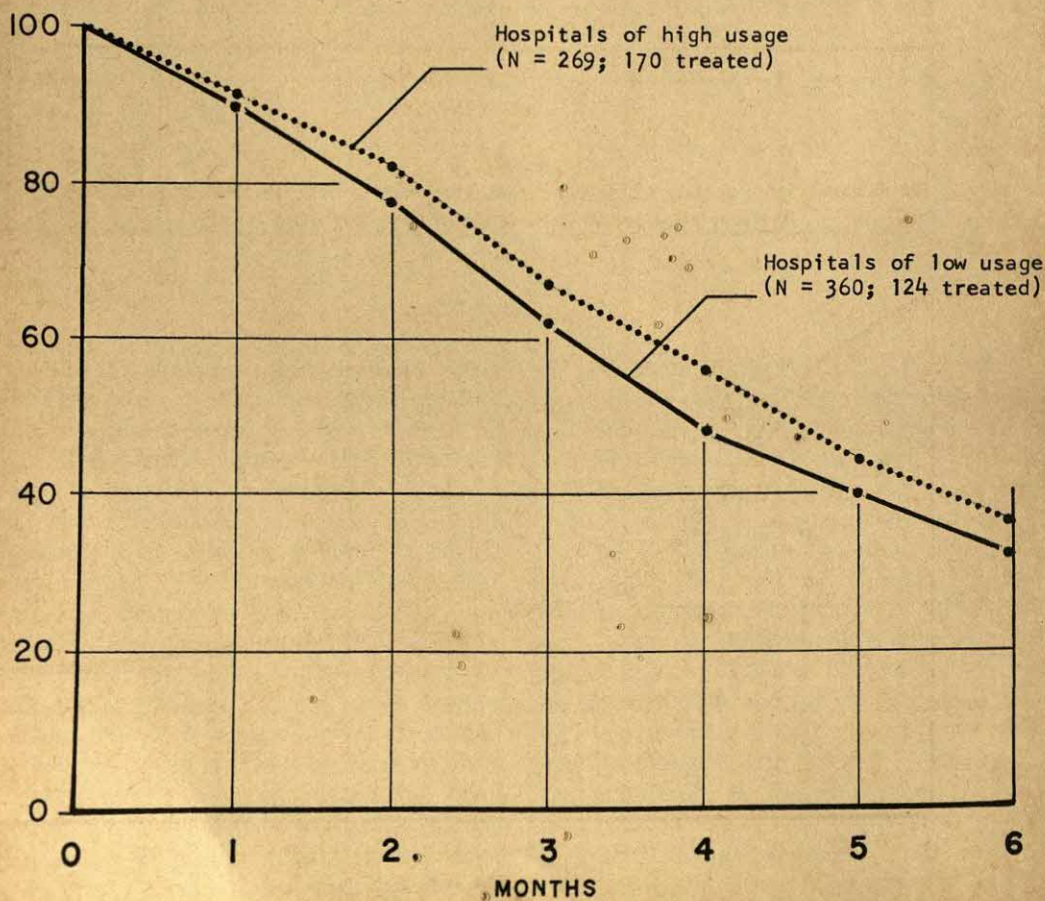

In each of these 2 hospital groups, one again notes that drug treated patients tend to have longer periods of hospitalization. The curves for the non-drug treated patients are consistently alike for the 2 groups. The drug treated group in the low usage hospitals, however, seems to have somewhat longer periods of hospitalization than do drug treated patients in high usage hospitals.

Figures 6 and 7 present these data for

FIGURE 8

The Retention Rates of Drug Treated and Non-Drug Treated Patients in Three Hospitals of High Drug Usage and Three Hospitals of Low Drug Usage—1957

PERCENT

the fiscal year 1957. A threefold increase in the amount budgeted for the purchase of psychotropic drugs resulted in an increase in the percentage of treated patients: 3 hospitals of high drug usage treated 63% of their cohort of admissions in 1957, and 3 hospitals of low drug usage treated 34%. It is noteworthy that the retention curves

FIGURE 9

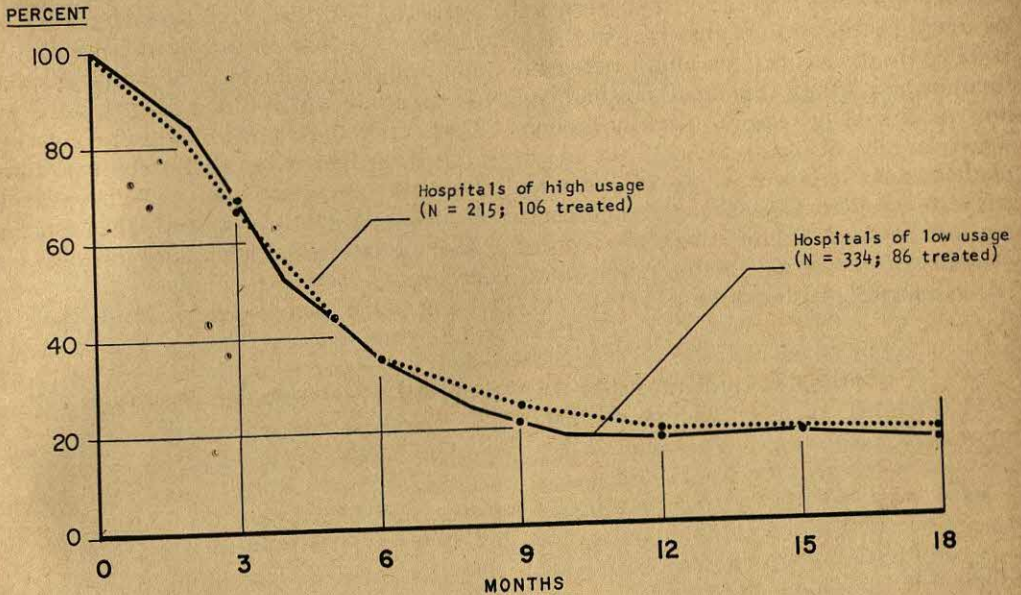

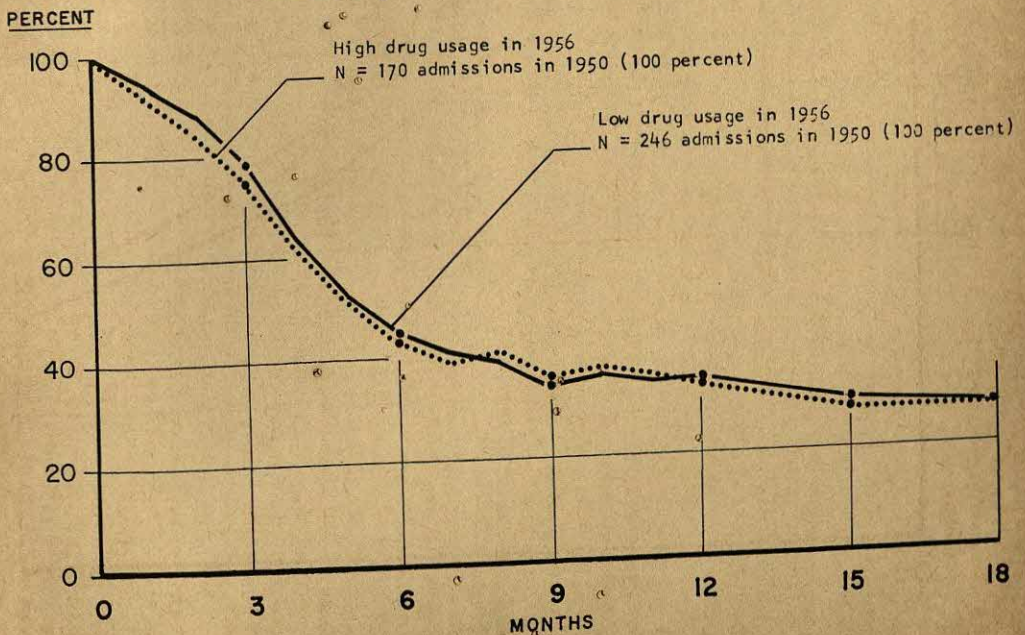

FIGURE 10
The Retention Rates of Male Schizophrenic First Admissions in 1950, to Three Hospitals with High Drug Usage and Three Hospitals with Low Drug Usage in 1956

for treated and untreated patients show much more overlap, both for high-usage and low-usage hospitals.

It appeared of interest to compare the high-usage and low-usage hospitals with respect to over-all retention rates for admissions in 1956 and in 1957, by combining the groups of treated and untreated patients for each admission year. The comparison is presented in Figures 8 and 9. For 1956, scarcely any difference was found between the 2 hospital groups, but for 1957 the hospitals of high-usage show a slightly higher retention rate.

If one examines retention rates for these hospitals for 1950 with this same patient category (Figure 10), one finds that these curves scarcely differ, thereby indicating little difference in the retention rates in high and low drug usage hospitals prior to the introduction of ataraxic drug therapy.

However, for treated and untreated patients combined, there is a notable difference for all California state hospitals between the retention rate for 1950 and the rates for 1956 and 1957, as may readily be noted in Figure 11. In addition, the data for the years 1951 through 1955 are available and are consistent with this trend.

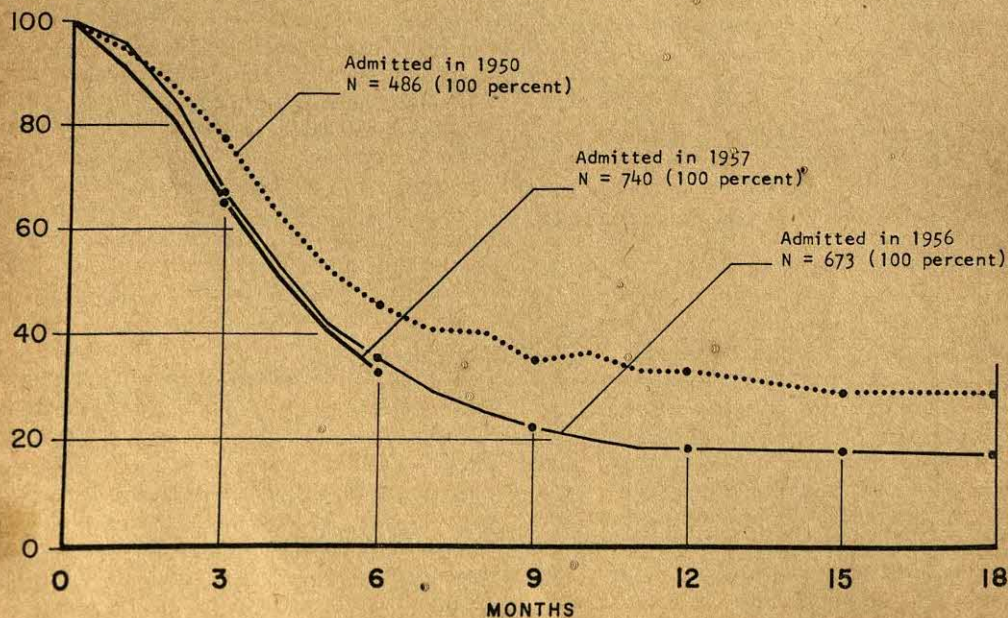

One may reach certain conclusions from these data insofar as the State of California is concerned. With respect to males diagnosed as suffering from schizophrenic reactions on their first admission, and insofar as ataraxic drugs were used in these hospitals during the 1956 and 1957 fiscal years, their usage does not appear to have been associated with the more rapid release rate which has been observed in recent years. It may well be, to be sure, that tangential factors associated with their use have resulted in an altered hospital environment with more frequent and earlier releases. Many other improvements and policy changes, however, have also occurred during these years, a factor which precludes unequivocal conclusions. The fact is, however, that with respect to the patient groups studied, where a difference is found between the retention rates of ataraxic drug treated patients and those not so treated, the untreated patients consistently show a somewhat lower retention rate. Furthermore, the hospitals wherein higher percentages of first admission schizophrenic patients are treated with these drugs tend to have somewhat higher retention rates for this group as a whole.

These would seem to be provocative data.

FIGURE 11

Retention Rates for Male Schizophrenic Patients, All Hospitals: First Admissions in 1950, 1956, and 1957

PERCENT

We intend to explore other groups in similar fashion. We have evidence in a controlled study which leads us to believe that ataraxic medication is effective with chronically ill schizophrenic patients. We intend to follow other patient groups in similar fashion for at least 5 years and plan to present results not only for these years but, hopefully, for medication in other years as well. In this fashion we hope to be able better to interpret the relationship between release rates and ataraxic drug usage.

DISCUSSION OF TWO PREVIOUS PAPERS

THOMAS D. GRIFFITH, M.D. (Brooklyn, N. Y.).—Statistical reports such as the 2 papers presented here do not always excite the same degree of interest and attention as reports of a more clinical nature, but it might be worthwhile to re-emphasize an old fact that the vast preponderance of psychiatric care and treatment has been, is being, and will be given in hospitals such as these reports are drawn from. It follows that the records of these institutions are repositories of a vast amount of meaningful information for evaluation of past and present treatment methods as well as for future planning. Drs. Brill and Epstein, along with their indispensable statisticians, have presented a good sample of the potential riches to be drawn from this source.

Dr. Epstein's paper presents some rather provocative data concerning a group of patients treated with ataractic drugs. As his tables show, the treated patients had lower release rates than the non-treated; also, release rates over the reported period were not significantly greater in the high drug usage than in the low drug usage hospitals. If we knew that the control groups were comparable to the treated groups as to degree of sickness, and if we knew that the drug dosage was adequate in amount and length of administration, we would have rather discouraging conclusions

to draw. However, Dr. Epstein's report, as he states, is a preliminary one and is to be followed by others in which more variables will be controlled. I hope these results which appear to be paradoxical will stimulate some lively discussion from the floor. My personal experience and impressions convince me that the psychopharmaceutical agents are a potent factor in earlier and increased rates of release. I certainly look forward to further reports from Dr. Epstein and his colleagues from California.

Dr. Brill has long had his finger on the statistical pulse of the New York State mental hospitals. Now, he has given us his third report since the beginning of the widespread use of psychotropic drugs 6 years ago. Dr. Brill is an astute and painstaking investigator and I find little to question in his observations and cautious conclusions. It is now clear that it is impossible to evaluate the effect of the psychotropic drugs as an isolated factor when so many other important changes in the hospitals and community have occurred concomitantly. As many observers have noted, the effects of these drugs have acted almost as a catalyst; the reaction appears still to be gaining momentum and spreading out until hardly any area of mental health is unaffected.

I was asked to discuss these papers from the point of view of an aftercare clinic psychiatrist. Our aftercare clinics, a facility of the New York State Department of Mental Hygiene, supply aftercare to any patients placed on convalescent care who reside in the 5 boroughs of New York City. These clinics stress intensive follow-up care by a psychiatrist and psychiatric social worker of both the patient and his family. Medication is continued without interruption in the transfer from the hospital to the clinic and is adjusted as necessary for maintenance. Close liaison is maintained with other community facilities such as the Department of Welfare, social agencies, vocational rehabilitation agencies, and other community clinics. Two of the four aftercare clinics have associated day hospitals. Through an intensive program including individual and group psychotherapy, pre-vocational training, occupational therapy and ECTs, where indicated, many chronically regressed and relapsing patients are kept from rehospitalization.

No report can be all-encompassing; encyclopedic as Dr. Brill's paper is, I believe he has not given the aftercare clinic its due, especially as to its effect on the hospital return rates and hence the hospital population figures generally.

Many of us in the field are convinced that eventually the mentally ill patient will, for the

most part, be treated in the community on an outpatient basis and the current trends in state hospitals will continue in the direction of this goal. Our clinics must in time expand to become before- as well as aftercare services. Practice, theory, and simple economics favor this trend. Even now, the aftercare clinics can show substantial proof of their efficacy. I would like to offer a few more statistics to emphasize just what our clinics are accomplishing.

The following data are taken from the annual report of the New York City aftercare clinics for 1959-1960 prepared by our director, Dr. Donald Carmichael. The figures are approximate. During the reported year 17,000 patients were placed in convalescent care from all the state institutions; of these approximately 9,000 attended the New York City aftercare clinics, the remaining 8,000 being followed by the aftercare clinics of their individual institutions. The rehospitalization rate in the New York City aftercare clinics was 34% and the rate for the other 8,000 was 50.8%.

Dr. Carmichael showed (and this emphasizes that intensive aftercare is a bargain) that the money thus saved in decreasing the return rate was about twice the total yearly budget of the New York City aftercare clinics.

At the Brooklyn Aftercare Clinic a few years ago, a one-year research study was done in which two of the clinic psychiatrists and their social work teams treated smaller case loads, and in which cases were picked up more quickly after hospital release and followed more intensively. We were able to reduce the rehospitalization rate to 17%.

There are some other factors which may further decrease rehospitalization but which I cannot, at this time, substantiate with figures. For example, the New York City aftercare clinics actively encourage selected patients at the time of discharge to seek private and low-cost clinic psychotherapy; we employ family physicians freely for medical supervision where continued medication is indicated, and our day hospital program is active, growing, and effective.

DONALD G. MCKERRACHER, M.D. (Saskatoon, Canada).—The papers of Dr. Brill and Dr. Epstein raise many questions. What do the fluctuations in mental hospital admission, discharge and resident rates actually mean? How have the new treatments, especially the ataractic drugs, affected these statistics? Does this picture not raise questions about the effectiveness of all state hospitals? With or without

the tranquilizers, should we continue to admit and keep within these huge institutions those who are confused, depressed, bewildered and anxious?

I shall first give my own interpretation of what Drs. Brill and Epstein are saying, and then agree or disagree according to my own experience. Dr. Brill has discussed mental hospital statistics of the past 10 years as collected in the State of New York. As in his 2 previous papers, he points out that after many years of annual increase, the total patient population suddenly began to drop. This sharp decline, which began in 1956, he links to the large scale use of ataractic drugs which had started 2 years previously. He also points out specific changes in the character of the mental hospital population toward fewer chronic schizophrenics, fewer younger patients, and more admissions with an even greater increase in discharges. Giving credit to the new drugs for triggering the changes, he challenges disbelievers to present proof to the contrary. Finally he attempts a projection of future New York mental hospital population, based on his study of the statistics of the past 10 years.

When I first compared the date of patient population decline in New York State with similar changes in Britain and Canada I thought I had discovered a discrepancy. The drop occurred in 1956 in New York, 1954 in Britain, and 1958 in Canada, even though all these areas began using the ataractic drugs during the same year—1954. However, this could be explained by the difference in the increase of population growth in the 3 areas. Therefore, it becomes clear that the decline in mental hospital patient rates per 100,000 commenced immediately after the new drugs were first used in Britain, Canada and New York State. So the evidence is overwhelming in support of Dr. Brill's claim that the fall in the mental hospital population is related to the wider use of the ataractic drugs.

However, I have to disagree with Dr. Brill's cautious suggestion that the effects are pharmacological. Until otherwise proven, I prefer to believe that the population fall can be attributed more to the effect of the publicity about these drugs or the attitude of staff and communities.

This view draws some support from Dr. Epstein's paper, especially where he shows that the retention rates of the hospitals which used the drugs but little were approximately the same as in the high usage hospitals. It seems to me that both groups of California hospitals described by Dr. Epstein might have been in-

fluenced by the clamour and the advertising which accompanied the drugs.

I would like to mention some of the disadvantages in using hospital population changes to establish drug effectiveness. Despite an amazing similarity in hospitalization changes in all areas and, even though the drop always came with the increased use of drugs, it must be made clear that other factors are involved in mental hospital population change. To illustrate, I want to compare the rates in Saskatchewan with those of Ontario during a 25-year period. From 1932 to 1958, the resident rate per 100,000 doubled in Saskatchewan mental hospitals (277 to 512), whereas the rate in Ontario, for this same period, remained almost constant (increasing only from 334 to 380). Here political, social and economic factors made much more difference than did drugs.

Further evidence of the future changes that may take place in mental hospital statistics comes from such projects as the Worthing Experiment, where the chronic patient load was kept at a minimum by home care and day patient treatment.

As another illustration of deliberately changing hospital statistics by planned policy I would like to describe a project in Saskatoon, a city of 100,000 people which sends its psy-

chotic patients to a 1200-bed mental hospital at North Battleford 100 miles distant. For several years, that hospital has contained about 275 Saskatoon residents and each year has admitted 125-150 acute psychotics from that city. For the past 6 months most of the patients, certified as mentally ill in Saskatoon, instead of going as formerly to North Battleford have been re-routed to a psychiatric ward in a general hospital right in the city of Saskatoon. Here they received intensive therapy and, with few exceptions, returned to their homes within 30 days; they are now being followed through a modified program of home care. It is too soon to report whether this policy is good or bad but that is not the point; enough to say that, at present, this program is radically changing the statistics of the hospitalization of psychotics from Saskatoon. This emphasizes the fact that there are many ways of looking after psychotics other than in chronic mental hospitals.

In conclusion: Whether one approves of the mental hospitals and whether we ultimately continue to have such institutions, the point is, we now have them and should learn from them. Studies such as those carried out by Drs. Brill and Epstein do much to increase our understanding of mental illness.

A SUMMARY DESCRIPTION OF FIFTY "NORMAL" WHITE MALES^{1, 2}

JULES GOLDEN, M.D.,³ NATHAN MANDEL, Ph.D.,⁴
BERNARD C. GLUECK, JR., M.D.,⁵ AND ZETTA FEDER, M.A.

Personality research in general, and psychiatric research in particular, has been seriously handicapped by the lack of uniformly accepted standards of normality. Until quite recently, the only generally accepted tests were the intelligence tests, where a range of normal intelligence, and ranges of subnormal and supranormal have been established for some years. None of the projective tests, Rorschach, T.A.T., *etc.*, has clearly established and generally accepted normal values or response patterns. Clinical psychiatric description tends to stress the presence or absence of abnormal patterns of behavior, symptoms, and disturbance of normal functioning, without an adequate description or agreement upon what constitutes "normal." Most of the studies reported in the literature deal with segments of personality functioning, as measured by one or more tests, by relatively brief interview; or with a highly selected sample. All of these factors limit the general applicability of the results, especially when one is attempting to set "normal" values.

In the past 15 years several very comprehensive studies have been reported, coming mainly from the highly selected groups represented by college students. In 1945 Heath(7) gave one of the first reports on the Grant Study, describing the general plan of this study of Harvard College sophomores. He states that 60% of the men examined had well integrated basic personalities, while the remaining 40% showed various symptoms such as shyness, mood fluctuations, autonomic instability, asocial

behavior, and incomplete integration of basic personality. It is interesting to note that only 6% of the group were felt to be motivated toward creative activity. Heath concludes that normal means a "perpendicular and balanced" personality.

In 1952 Earl Bond(2) reported on 64 of 66 student council members in 3 colleges in the Philadelphia area. In spite of the opinion of one of the college presidents, "It is as normal a group as you will get," only 39 of these students were judged to be well balanced, or to have such strong assets as to outweigh their liabilities. Sixteen of the group showed extraordinary ability and important neurotic traits, "success at the price of unhappiness." Nine of the group were described as gifted, but with serious personality problems: schizoid, depressive, *etc.* Bond concluded that 57% would benefit from psychiatric help, while 14% were in urgent need of help. In discussing the concept of normality Bond stresses a number of negatives, things that normal is not: *e.g.*, "Normal does not mean average—normal does not mean uninteresting—normal is not perfect—a normal person is not one who has no problems." He concludes with several positive statements about normality; it has a wide range and is in a state of flux; normal people are free to focus their energies on main purposes; and in their own culture normal people work and love with ease, happiness and efficiency, somewhat in proportion to their circumstances.

In a paper in 1956, reporting on projective test responses of the same group of students, Cox(3) defines normality as "the ability to maintain an harmonious and productive relationship with the environment and with the self." This is very close to the definition of normal inferred by Ackerman(1) as part of a discussion of goals in therapy. He sees the mentally healthy individual functioning harmoniously in 3 areas: in his internal economy of personality, in his interpersonal adaptation with his significant

¹ Read at the 117th annual meeting of The American Psychiatric Association, Chicago, Ill., May 8-12, 1961.

² This research was conducted in the Dept. of Psychiatry, University of Minnesota Medical School.

⁴ Dir. of Research, Dept. of Correction, State of Minnesota.

⁵ Dir. of Research, Institute of Living, Hartford, Conn.

small group, usually the family, and in his relationships with larger social community.

Epstein(4), in describing some of the problems encountered in a family research study, discusses a number of concepts of normality or emotional health, including the one given by Ackerman, quoted above. On the basis of these various definitions Epstein and his colleagues divided their cases into 4 groups :

A. Absence of structured psychiatric symptoms, adequate social and occupational adaptation, no impairment of dynamic integration.

B. Absence of structured psychiatric symptoms, adequate social and occupational adaptation, mild impairment of dynamic integration with mild anxiety.

C. Absence of structured psychiatric symptoms, presence of social and/or occupational maladaptation, moderate impairment of dynamic integration with moderate anxiety and psychopathology.

D. Structured psychiatric symptoms, social and occupational maladaptation, severe impairment of dynamic integration with severe anxiety and psychopathology.

Groups A and B were considered to be emotionally healthy, although perhaps not normal.

From all of the foregoing material it appears to be obvious that a specific statement of what the normal or emotionally healthy person is like is still in its infancy. The definitions given all imply a large element of subjective evaluation and judgment on the part of the investigator or observer, and suffer inevitably from the various defects inherent in such an appraisal. In an attempt to avoid some of these problems of distortion by the observer, we have utilized the Minnesota Multiphasic Personality Inventory, which is a self-description type of evaluation, as the basic instrument for determining the subjects to be included in this study.

The problem of selection of subjects is never more important than in a study of this type. In all of the groups described above, and in several other reports on "normal" groups, including one on "normal control" volunteers, by Pollin and Perlin(9) in 1958, and a recent report on drug study volunteers by Esecover, Malitz and Wil-

kens(6), a high incidence of psychopathology is reported. All of these considerations helped to determine the design of the current project, and the method of case selection.

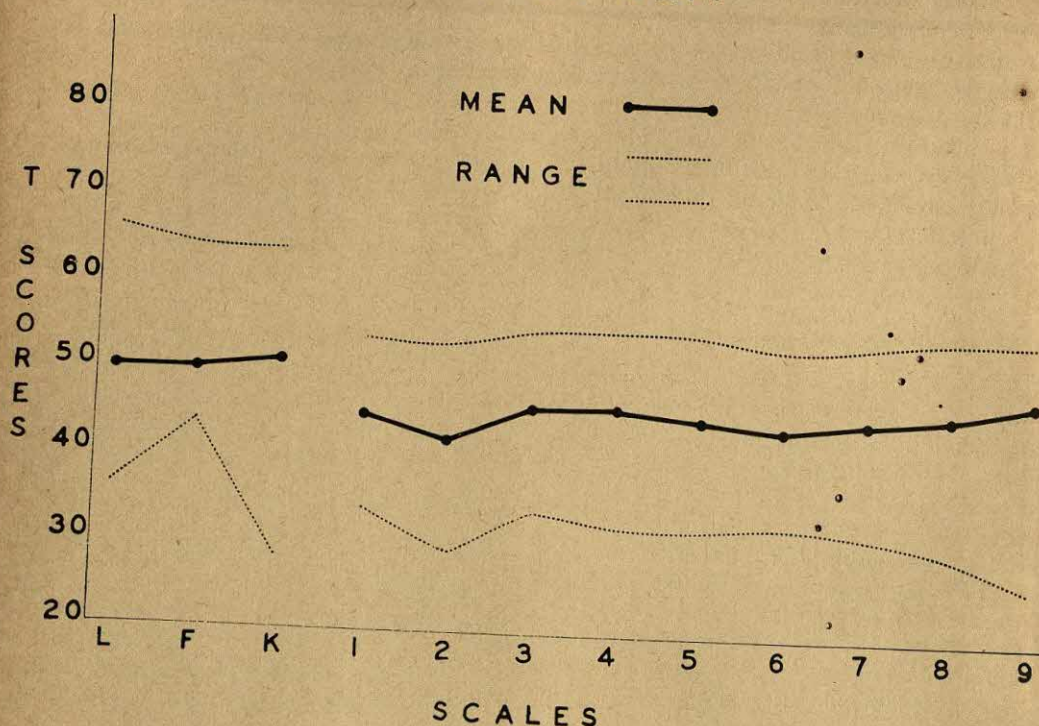

This study of "normal" young males was undertaken primarily to provide a reference group for a study of 100 psychiatric patients, part of a project studying "The Skilled Clinician's Assessment of Personality." We were able to draw upon a large group of young adult males who had first been studied 12 years previously, as part of a project on delinquency being conducted by Monachesi and Hathaway of the University of Minnesota. They had obtained a self-descriptive evaluation, by means of the MMPI, of all ninth grade students in the Minneapolis public schools. These individuals have been followed periodically in the succeeding 12 years, so that those developing known mental illness or delinquency patterns have been identified, and were readily eliminated from our sample. We took as our basic group those individuals who, on self-description at approximately age 14, had indicated an absence of psychopathology in any of the areas measured by the MMPI. This is indicated on the MMPI results by a profile with no score above 55.

Of 1,953 male students tested, 73 gave no indication of significant pathology. Of these 73 potential subjects, 23 were excluded from the study for the following reasons : 13 had moved out of the state, 7 were not locatable, 1 was deceased, 1 could not leave his job in a distant part of the state to come in for interview, and 1 subject refused to cooperate. Of the 50 remaining subjects, all but 5 agreed quite readily to assist in the project. These 5 were primarily concerned about the economic loss occasioned by leaving their jobs, and were persuaded quite readily when they were told they would be recompensed for the time spent in the interviews.

Each subject was seen for evaluation at the University. The following procedures were carried out :

1. A 1½-hour unstructured psychiatric interview in which current adjustment, description of home of origin, personal history

FIGURE 1
ORIGINAL MMPI

and aspirations, and mental status were appraised.

2. Examination on additional material to cover an extensive check list type of psychiatric history.

3. A structured mental status examination (check list).

4. A social adjustment rating (MSAS).

5. Psychometrics: (a) Repeat of the Minnesota Multiphasic Personality Inventory (MMPI); and (b) Projective drawings (House-Tree-Person) (HTP).

6. A home visit and unstructured interview with the wife, which included the wife's evaluation of her husband, and the interviewer's evaluation of the wife. (The MMPI, MSAS, and HTP were administered to the wife as well.) The wives of 38 of the 40 married men in the sample were interviewed.⁶

Findings: Our first impression, and one that has continued through subsequent evaluation of the data obtained, was of a remarkable consistency and uniformity in

the sample of 50 men. On most of the items in the extensive psychiatric history, these men were rated either identically, or within one step, on the variables involved. Some of the similarities were directly influenced by the choice of subjects; for example, 49 of the 50 subjects were born and raised in the Middle West, all were in the 25- to 26-year age range, 48 were currently living in a large metropolitan area.

Some diversity occurs when the current adaptational patterns are examined: 11 men were engaged in professional or semi-professional technical work, 2 were in executive positions, 12 were clerical, sales, or other white collar workers, 13 were craftsmen, skilled workers, or foremen, and 12 were operatives and semi-skilled workers. None was in the unskilled, laboring, service, or domestic categories. A narrower spread is observed in their income levels. Only one man was in the \$10,000 to \$14,000 a year class, 14 were in the \$6,000 to \$10,000 category, 34 were in the \$3,000 to \$6,000, and only 1 was earning under \$3,000 a year. All of the men had completed high school, 15

⁶ The complete data from this study will be on file with The American Documentation Institute.

had some college education, while 7 had postgraduate education.

The spread becomes somewhat wider when the observers' evaluations of these individuals enter into the picture. On the mental status examination these men were rated as having a spread of from 6 to 40 positive items, with a mean of 22.3 items. This contrasted with a spread of from 1 to 5 negative items, with a mean of .52 negative items per subject.

1-5	0	13
0	0	37
Mean/Subject	22.3	.52

The social adjustment of the subjects was assessed quantitatively by using the Mandel Social Adjustment Scale(8), which gives a quantitative measure of the extent to which an individual meets the overt societal norms of his society. A score of 5 on each of the subcategories of this scale would mean a perfect adjustment. These men had a mean

score of 4.43 on the combined 7 scales, with a low of 3.84 on the scale measuring religious adjustment, and a high of 4.80 on the scale measuring health adjustment. This compares favorably with the scores obtained on 3 other groups of subjects as indicated in Table 2.

The current MMPI profiles of the subjects were rated by a panel of 5 psychologists, again on a 5-point scale, with a rating of 5 indicating the most healthy end, and a rating of 1 as the most pathological end. Three subjects were rated 5, 23 between 4 and 5, 18 between 3 and 4, 5 between 2 and 3, and 1 between 1 and 2, with a group mean of 3.82.

An appraisal of the overall adjustment of the married subjects, based on the data obtained from the interview with their spouses, was made independently by 3 social workers. Identical ratings were given 19 of the subjects, another 18 subjects were rated identically by 2 of the 3 judges, and only one step off by the third, while in only one case was there lack of agreement between at least 2 of the 3 raters. Two of the men were not rated due to insufficient information, and none of the 10 unmarried subjects was evaluated. The mean rating obtained was 3.16 on a 5-point scale, with a rating of 5 being the ideal, again showing relatively good adjustment. The subjective impression of the 3 raters was that they were confronted with a particularly "normal group of people."

DISCUSSION

Looking at the last table, showing the distribution of the men by diagnostic categories, one might question the validity of the selection process described above for choosing these men. We would like to raise the question, however, as to whether the "range of normal personality" should not include 47 of the 50 men examined. If we evaluate these individuals on the basis of the various definitions of normality described earlier in this paper, we believe that all but 3 of the men would fall within the normal groupings given by the various authors. For example: if we attempted to place our subjects in Epstein's 4 categories, we would find that in addition to the 23 men with no evidence whatsoever of symptomatology, 18% listed in the various diagnostic groupings with minimal disturbance would be consistent with category A, since none of these individuals showed structured psychiatric symptoms, disturbance of social or occupational adaptation, or disturbance of their dynamic integration. About 20% of the men would be placed in group B, because of mild impairment of

their dynamic integrity with the appearance of some anxiety or its equivalent. One subject with a current history of peptic ulcer, and 2 subjects who showed some antisocial patterns, particularly in traffic violations, might be placed in group C because of the social and occupational maladaptation present. Only 2 men, one with moderately severe pseudoneurotic schizophrenia, one with an obsessive-compulsive pattern, could be said to have definitely structured psychiatric symptoms and the other disturbances of adaptation described in group D. Thus, 45 of the men in our sample would probably be considered by Epstein to be emotionally healthy, within the broad range encompassed by his use of that term.

If we appraise these men from the standpoint of Ackerman's criteria, 70% of the men would appear to have an essentially harmonious relationship in the 3 areas described; 30% showed varying degrees of difficulty, primarily within themselves, although in 2 instances the main disturbances were in the significant small group relationships, and in 3 others in the relationship with the larger social group.

If we assume that any symptomatology is evidence of a need for treatment, we would find that 54% of our sample would be in this category, as compared with 57% reported by Bond. However, we would see only one subject as requiring psychiatric help in order to continue some kind of successful adaptation.

It is also interesting to consider some generalizations about the characteristics of the

group, not only as evidence of a current "normal" or "appropriate" adaptation, but also as a prediction for the future involving the impact of these men on their families. The major focus of interest of the subjects appears to be in the home. Those who were married expressed a high order of contentment with their wives and children. There were no separations or broken marriages; with one outstanding exception, the men tended to idealize their wives and the wives were, again with one exception, content with their husbands as stable, responsible, dependable, supportive individuals. If the findings of Epstein and Westley (5) that suggest that the emotional health of children is influenced primarily by the nature of the conjugal relationship are applied to our married men and women, we would predict that the children of the married subjects should develop in a healthy fashion, since the conjugal relationship seems to be so satisfactory in 39 of the 40 married couples.

The marked vocational and residential stability which is characteristic of this group, and the general lack of significant psychopathology, may perhaps be achieved at the price of a more creative, spontaneous type of personality organization. These men were found to have little imagination, and generally limited interests and social activities. They indicate limited educational and vocational aspirations for themselves, and also for their children. This was reflected in the ratings given on various subitems of the psychiatric interviews, with

TABLE 4
Descriptive Categories

- I. Contentment with vocational position: Satisfaction with job level and activities.
- II. Enjoyment of occupation: Extent of pleasure derived from job and associated activities.
- III. Vocational ambition: Vocational goals and aspirations (in relation to estimated abilities and opportunities).
- IV. Parents' previous concern with subject's vocational development: Parents' role in influencing subject's vocational choice and progress.
- V. Contentment with spouse: Satisfaction with choice and relationship with spouse.
- VI. Compatibility with spouse: Comfort in relationship with spouse.
- VII. Effectiveness as a husband: Assumption and performance of the role of head of the household.
- VIII. Effectiveness as a parent: Assumption and performance of parental role.
- IX. Means of handling anger: Mode of expressing assertion and dissatisfaction.
- X. Symptoms: Manifestations or organized psychopathology.
- XI. Wishes for 10 years hence: "What would you wish in 10 years if you could write your own ticket?"
- XII. Use of unlimited finances: "What would you do if you were given \$5 million with no strings attached?"
- XIII. Breadth of interests and pleasures: Range of pleasure yielding activities.
- XIV. Richness of personality: Subject's positive social stimulus value.
- XV. Overall mental health: Degree of adaptational behavior, considering both personality assets and deficits.

richness of personality and breadth of interests and pleasures being the 2 lowest ratings of the 15 descriptive categories. Contentment with spouse and compatibility with spouse were the two highest ratings, with enjoyment of occupation, and contentment with vocational position also being very high on the list.

CONCLUSION

All of the above raises in our minds a question which has been stated in a number of different ways in the past concerning the balance between the needs and the wants of individuals on the one hand—in this group apparently very much in balance—and the various factors that have been considered to be part of the richer, more creative, spontaneous type of personality. Does "normality," as evidenced by lack of intrapsychic tension, adequate social, economic and familial adaptation, and harmonious integration with other individuals at all levels, necessarily imply a lack of creativity, imagination, and spontaneity? Our data are suggestive of this conclusion. Confirmation would be dependent upon a study of those individuals in the original sample of 1,953 male ninth-graders who have subsequently been more creative, although they showed evidence of some disturbance at that time as measured by their

MMPI profiles; at the very least.

It is our opinion that the 23 subjects described in this study as being free of symptomatology and as having made a stable, successful adaptation, represent a very normal, healthy, socially acceptable and desirable group of individuals. We would feel that an additional 12 subjects represent the broader "range of normal," which allows for some degree of intrapsychic tension and some minimal adaptational difficulties, none serious enough to interfere with a basically adequate and successful social and economic adjustment. The remainder of the group, with 2 exceptions, while having somewhat greater difficulty in making an adaptation, are still quite successful in most areas and will probably continue to make a successful adaptation without psychiatric help, although perhaps at the cost of greater tension and psychic stress and strain than might otherwise be the case.

The authors believe that the characteristics of this group of subjects are consistent with a general conception of the well adjusted average American male. Further, that these multi-dimensional data provide a meaningful baseline of personal adaptation within contemporary American society to which other groups may be compared.

DISCUSSION

N. B. EPSTEIN, M.D. (Montreal, Canada).—I would like to congratulate the authors on their courage in venturing into this field of study, which seems to repel scientific investigators. The reasons for this avoidance include : (a) the complexity of the problems ; (b) the lack of adequate methodological techniques for tackling them ; and (c) the subject is laden with emotion due to the inherent value judgements necessarily involved. The investigator venturing into this field automatically becomes a target for attack by all sides.

I wonder whether in the attempt to avoid observer distortion, the authors have not merely substituted the distortions by the MMPI for the distortion by human observers. The authors have demonstrated that the MMPI is a reliable test, *i.e.*, it measures what it does measure with consistency. In my opinion, however, it is doubtful whether it has been shown categorically that this test is a valid test for the measurement of "normality," or, to use a term I prefer, "emotional health." At the present level of development in this field, no one test could be validated for the measurement of "normality" or "emotional health" for the simple reason that there is as yet no agreement as to what constitutes such emotional health. At best, it can be said that a given test might measure some elements, which some observers might agree constitute an acceptable definition of emotional health.

In the present study the authors *a priori*

accept certain results on the MMPI as denoting normality, *i.e.*, those subjects having a profile on the test with no score above 55. They selected 50 subjects meeting these criteria and proceeded in a well designed program of psychosocial investigation. They then report the results of this investigation as being characteristic of "normality." One can only agree with this conclusion, if one agrees with the authors' *a priori* acceptance of certain results on the MMPI as denoting normality.

The results strongly indicate that according to the criteria accepted by the authors the test measures primarily the factor of adjustment. They state, "the authors believe that the characteristics of this group of subjects are consistent with a general conception of the well-adjusted average American male." They imply in several places that a well-adjusted person is a normal or a healthy person. If one accepts this equation of adjustment with normality or emotional health, there is no argument. However, it is on this point that I am sure the authors will meet with a high degree of controversy.

Many writers have noted that adjustment cannot always be equated with emotional health, but that often a high psychic price is paid for such adjustment. Such writers give a more extended statement as to what is involved in emotional health. The present authors have mentioned several such statements and definitions. Bond(1) is quoted as stating : "Normal does not mean average—normal does not mean uninteresting—normal is not perfect—a normal person is not one who has no problems."

The authors obviously recognize this problem and question whether adjustment is equatable with emotional health. They note "The marked vocational and residential stability which is characteristic of this group, and the general lack of significant psychopathology, may perhaps be achieved at the price of a more creative, spontaneous type of personality organization. These men were found to have little imagination, and generally limited interests and social activities. They indicate limited educational and vocational aspirations for themselves and also for their children." They raise the following basic and most important question : "Does adequate social, economic and familial adaptation, and harmonious integration with other individuals at all levels, necessarily imply a lack of creativity, imagination and spontaneity?" They answer this question by stating : "Our data are suggestive of this conclusion." On the basis of our experience in this same general area over the past 6

years in the McGill Human Development Study, I feel that the reason the data in this report are suggestive of the above conclusion rests in the methodological trap in which the authors have been caught by their implicit equation of "adjustment" with "emotional health." This in turn results from their *a priori* acceptance of certain results in the MMPI as indicating "normality" or "emotional health."

In our study we were unable to discover a test procedure which would in itself give a satisfactory measure of emotional health as we defined it(2). We found it necessary to develop a schema to classify and rate emotional health. This schema depended upon findings derived from intensive psychiatric interviews and various projective techniques given to our subjects. This schema is reported in detail in this paper.

Before such a schema could be developed it was necessary to agree among ourselves upon a satisfactory model of emotional health, the developmental basis of which we reported in some detail(2). This model is too complex to discuss now, but it was largely based on a previous model developed by Jahoda(3). Jahoda suggested that a combination of the following 3 criteria be used for the determination of emotional health:

1. "Active adjustment or attempts at mastery of his environment as distinct both from his inability to adjust and from his indiscriminate adjustment through passive acceptance of environmental conditions.
2. "Unity of his personality, the maintenance of a stable, internal integration which remains intact notwithstanding the flexibility of behaviour, which derives from active adjustment.
3. "Ability to perceive correctly the world

and himself."

The model developed by us requires that the individual strives to fulfill his psychobiological and social endowments to an optimal level whenever and wherever possible in order to meet the criteria of emotional health. In this type of model, passive, indiscriminate adjustment is not equated with emotional health. "Normality" as defined in this model does not imply a lack of creativity, imagination and spontaneity. We are not yet satisfied that our model is complete; it is still primitive and demands further development. What is needed is the development of a comprehensive list of the endowments of the human organism. Once this is attained, it should be relatively easy to assess whether and to what degree the individual fulfills his endowment. It is our belief that there already has been a sufficient accumulation of data in the behavioral sciences to begin moving forward once agreement has been achieved as to the basic principles involved.

The paper being discussed is an excellent example of the work that can and should be done. The criticisms I have raised in no way devalue the fine work of the present investigators. They are merely intended to outline in further detail the problems and obstacles faced by those venturing into this complex field.

AMNESIA : A CLINICAL STUDY OF NINETY-EIGHT CASES¹

THEODORE A. KIERSCH, M.D.²

Amnesia is defined as loss of memory, and is a clinical symptom which is seen in a variety of conditions. It has been exploited in that field of literature which deals with crime, detective stories, and fiction. It has always been considered one of the easiest symptoms to simulate, and one of the hardest to disprove.

A review of the existing literature(1-13) reveals conflicting statements about the nature of the origin of amnesia and the characteristics of various types of amnesia. It was consequently felt that a need existed for a more tangible method of differentiating the various types of amnesia, and for statistical data to support the diagnostic criteria for various types of amnesia.

Forty-five frequently listed characteristics of various types of amnesia were compared in over 100 cases claiming current or recent past amnesia admitted to a hospital during the past few years. Each case was evaluated from a careful historical viewpoint to record in detail the various claimed characteristics of the amnesia and to evaluate the pre-amnestic personality. Attempts were made to obtain as much collateral information as possible to evaluate the circumstances surrounding the development of the amnestic symptoms as well as the actual behavior of the individual during the alleged amnesia. Each case was also completely examined in repeated interviews, physically, neurologically, and each received an electroencephalogram, a complete battery of psychological tests and underwent attempts at hypnosis and, finally, was examined under the influence of amytal.

To date, 125 cases with amnesia as a prominent symptom or the presenting complaint admitted to one of two army general hospitals were included in this study.

The first 30 cases were evaluated in the form of a pilot study, and from this it be-

came apparent that some modifications in the study were necessary. For instance, it was determined that amytal interviews as well as hypnosis were necessary to evaluate the amnestic symptom; 12 cases in which the amytal interview had been omitted had to be dropped because of this fact. Fifteen additional cases, originally included in the study, had to be dropped because some were dependents who refused to participate and a few patients went AWOL before the study was completed. This report, therefore, concerns the remaining 98 completed cases.

Patients who presented a history of brief amnesia with a seizure or who had witnessed seizures were excluded because a similar type study with suspected epileptics had been previously reported(13). The patients included in this study were otherwise selective only in that the majority were relatively young military male personnel. The final group includes only 6 females who were either on active duty (WACs) or were civilian dependents of military personnel. The study patients varied in age from 19 to 45 with the majority in the 21 to 30 age group.

FINDINGS

The detailed study of these 98 cases and attempts to classify them led to the conclusion that there were in fact 4 main categories of amnesia and some identifiable sub-categories. Figure 1 presents the overall results as well as a proposed system of classification.

Included in the feigned category were those cases which, in the course of the study, admitted under hypnosis or amytal, that they were in fact feigning amnesia, and explained the reasons on a logical reality basis. Of the 41 cases in this category 25 subsequently admitted in a conscious awake state that they were feigning amnesia; 16 of the 41 cases would not and did not subsequently, in an awake state, admit that they had feigned amnesia. In spite of the fact that the patient was under hypnosis or amytal, the admission was accepted

only after a logical reality oriented reason was offered for feigning.

In the psychogenic group (20 of the 98 cases) 15 fell into the so-called classical psychogenic dissociative or fugue-like state, utilizing the unconscious mental mechanism of repression. Five of the 20 were psychogenic amnesia cases who, because of some severe reality factors, apparently consciously told themselves they would not remember. These 5 individuals invariably ran away from a traumatic situation, and successfully consciously induced amnesia in that although they initially told themselves that they would not remember, they subsequently believed and behaved as though they were amnesic. These 5 cases apparently utilized the conscious mechanism of suppression. It is this group that accounts for the difficulty in distinguishing malingering from true amnesia. Although this group may be considered borderline, they differ from the feigned group in that because of the successful use of suppression they were not lying when they said they did not remember. They believed they did not remember. The majority of the feigned group, however, eventually admitted they did remember and admitted that they had been lying.

The organic group included a whole variety of causes including trauma, cerebrovascular diseases, gunshot wound of the head, Korsakoff's, and simple alcoholism. It is interesting to note that none of the cases of amnesia included under simple alcoholism lasted more than 28 hours.

The fourth and last main group is la-

belled mixed because it consisted of various combinations of the above 3 factors. The largest single group in the mixed group was 8 cases of alcoholism plus exaggeration. These cases were individuals with some true toxic organic alcoholic amnesia but invariably involved periods of many days to weeks or months. It was determined that although these persons were amnesic for periods within the alleged prolonged amnesia, they invariably did have memory for periods when they would awaken in a strange town or awaken from sleep and have recall for that period of time until they began drinking excessively again. One conclusion reached from the study of amnesia associated with alcoholism was that the true acute toxic or alcoholic amnesia last only while the individual is under the influence of significant amounts of alcohol. All alcoholic cases claiming amnesia for many days proved to fall in the mixed group which includes exaggeration or feigning in addition to true brief periods of amnesia. Another category in the mixed group that deserves special comment is the psychogenic plus exaggeration. There were 5 patients in this group. Again based upon the study, it was learned that a true psychogenic amnesic repression-type episode occurred which may have lasted minutes to an hour or two, but the patients exaggerated and claimed amnesia for considerably greater lengths of time. It was as if there was a conscious effort on the part of the patient to make the psychogenic amnesia yet more remote by enlarging the period of amnesia. Obviously other possible combinations of mixed amnesias exist, such as organic plus psychogenic, or all 3 types in a single case; however, in the reported study apparently by chance these did not occur.

Of the various claimed amnesic settings and characteristics a few lend themselves to analysis and some possible conclusions or assumptions. None of the following examples is presented as conclusive, irrefutable characteristic of any one type of amnesia, but some very obvious trends can be identified. Of the 98 cases, 32 were hospitalized who were under court-martial charges or were being investigated for alleged offenses that would in all probability result in legal action.

FIGURE 2

I. Feigned

III. Organic	
A. Organic brain syndrome	1
IV. Mixed	
A. Alcohol plus exaggeration	7
B. Psychogenic plus exaggeration	2
Total	32

Figure 2 shows the breakdown of these 32 cases. It is quite apparent from this that 21 of the 32, or 66% fall into the feigned group, 1 into the true organic group, 1 in the psychogenic suppression group, and the remaining 9 into the mixed or questionable group. From this study one might conclude that anyone in serious legal difficulty who claims amnesia will prove to have either a feigned or questionable amnesia.

Thirty of the 98 cases were quite suggestible and could be hypnotized to a relatively deep trance.

FIGURE 3

I. Feigned	13 of 41

A. Organic brain syndrome	5
B. Toxic state	1
IV. Mixed	0 of 13
Total	30

Figure 3 breaks this group down into the various types of amnesia. It is obvious that no remarkable conclusions can be drawn. Fifty-five percent of the psychogenic amnesia cases could be hypnotized, and 22% of the feigned amnesia cases. Certainly there is a trend here, but this is not felt to be conclusive.

Another characteristic that was cross-checked against these 98 cases was the inconsistencies in the patients' histories as related to various examiners, or demonstrated to the same examiner during subsequent interviews.

Figure 4 shows the breakdown of this

FIGURE 4

I. Feigned	15 of 41
II. Psychogenic	5 of 20
III. Organic	2 of 24
IV. Mixed	5 of 13

characteristic by type of amnesia. Again, a trend is readily visible, namely, that inconsistencies are most prominent in cases of feigned amnesia, and the questionable mixed types.

Of the 98 cases, 13 claimed or demonstrated a loss of personal identity. Figure 5 indicates that this characteristic occurred in all groups in reasonably proportionate numbers and demonstrates no significant trends.

FIGURE 5

Feigned	4
Psychogenic	5
Organic	3
Mixed	1

Of the 98 cases, 20 claimed head injuries. Figure 6 indicates that if we exclude those cases of known severe head trauma with neurological findings, skull fractures, coma, etc., all other cases claiming head injury fell into the category of feigned or the questionable mixed group.

FIGURE 6

I. Feigned	10
II. Psychogenic	0
III. Organic	8
IV. Mixed	2

An attempt was made to evaluate the pre-amnestic personality and correlate this with the type of amnesia finally determined to exist. As may be expected, a higher percentage of character and behavior disorders were found in the feigned group, and a higher percentage of immaturity reactions were found in the psychogenic group. The figures demonstrated, however, only a moderate trend and were not felt to be conclusive.

In each case the intelligence was measured. This also proved to be of little or no value. The range was 69 to 125 in the feigned and mixed group, and 67 to 132 in the true amnesia group.

The EEG studies were of relatively little value: 30% of the organic group had grossly abnormal EEGs as might be expected. The incidence of borderline or abnormal

EEG in the other 3 groups was equivalent to the expected rate of chance abnormality in the average population.

Each patient was given a complete battery of psychological tests, including the Rorschach, Wechsler-Bellevue, MMPI, Bender Gestalt, Picture Frustration Study, and Level of Aspiration Test.

A detailed statistical analysis of psychological test variables yielded no significant results. Attempts were made, for example, to correlate the various groups with such things as the F score on the MMPI. There appeared to be no correlation. Of course, psychological examination was an invaluable aid in evaluating the subjects' personalities and as an aid to final diagnosis.

Other characteristics such as duration of the amnesia, retrograde or anterograde features, recurrences, amnesia for friends, preservation of non-personal memory, double personality, type and rapidity of recovery, resistance to hypnosis and apparent lack of concern over what the patient did while amnesic, when cross-checked against the various types of amnesia revealed no consistent findings. A few additional general comments may, however, be applicable.

Twenty-three of the 25 cases of admitted feigned amnesia claimed or demonstrated rapid recovery from the amnesia. Fourteen of the 15 cases of the psychogenic repression-type never could or would consciously recall the events which occurred during the amnesic episode; 3 of the 5 psychogenic suppression-type cases did eventually recall. None of the 20 organic amnesias could recall completely the amnesic episode although the duration of the episode could be shortened, *e.g.*, the retrograde portion of the amnesia in head injury cases could be recalled or significantly decreased in duration.

CONCLUSION

This study began as an attempt to identify common characteristics of various types of amnesia. The study demonstrated some significant trends for certain characteristics to be present or claimed in various types of amnesia. However, the study did demonstrate the need for a new system of classification. Such a classification is proposed, consisting of 4 main headings with a few

sub-categories under each main heading.

COMMENT

Extensive use in this study was made of hypnoanalysis and narcoanalysis. One or more hypnotic sessions were attempted in each case. A permissive hypnotic approach was used. Every case was subjected to an amytal interview using sodium amobarbital intravenously. The minimum amount used was 6 grains (0.36 gr.) and the maximum 22½ grains (1.5 gr.). The average patient was given 10 to 15 grains of amytal and the interviews lasted from 30 minutes to 2½ hours. The amytal interview was conducted only after as much collateral information as possible could be collected in order to check the information obtained under amytal against known facts. Every effort was made to be objective and not suggest answers to the patient. No physical complications arose as a result of the amytal interviews.

ACKNOWLEDGEMENT

Credit for the original plan for this investigative work, and the evaluation of the majority of the cases in the pilot study is due to P. G. Yessler, Lt. Colonel, M.C. and D. B. Peterson, M.D.

MODEL PSYCHOSES AND SCHIZOPHRENIA¹

ELLIOT D. LUBY, M.D., JACQUES S. GOTTLIEB, M.D.,
BERTRAM D. COHEN, Ph.D., GERALD ROSENBAUM, Ph.D.,
AND EDWARD F. DOMINO, M.D.²

INTRODUCTION

The intact, normally functioning, awake organism operates in a milieu from which a dynamic flux of input stimulation is continually received. Adaptive organismic accommodation to this input entails: 1. A receptor system for external stimuli; 2. A receptor system for internal stimuli including those from muscle, joints, and viscera; 3. A system for filtering the diverse sensory input and integrating and interpreting it; 4. An effector system involving autonomic and volitional motor acts; and 5. A chemical energy production system necessary for the adequate evocation of reactions in each of the separate systems mentioned.

If psychotic behavior involves alterations in the functioning of these systems, then experimental techniques that alter them in control subjects should produce psychotomimetic effects. To evaluate this proposition, we have conducted a series of studies in which psychological disorganization was acutely induced by means of (1) sensory isolation, (2) drugs, (3) sleep deprivation, and (4) combined sensory isolation and drugs in control subjects. A comparable series of observations was obtained when chronic schizophrenic patients were subjected to some of the same experimental conditions. The object of these studies was to attempt to isolate the phenomena pertinent to the understanding of the schizophrenic process from the epiphenomena associated with the experimental state. In this way we were attempting to overcome the objection that model psychoses as artificial states do not implicate mechanisms of the naturally occurring illness.

SLEEP DEPRIVATION

Sleep deprivation has served as one of the more useful model psychoses because

its gradual development and comparatively long duration allow for the study of a number of response systems. Luby, *et al.*, sleep-deprived 12 non-psychotic men for 123 hours and studied behavioral, psychological, biochemical, and autonomic changes (1, 2, 3).

The behavioral sequelae were very similar to those described by Tyler (4), Williams, *et al.* (5), and Brauchi and West (6). Lapses in attention and ongoing behavior, related to Morris, *et al.* (7), to brief periods of sleep or drowsiness, were common to all subjects. Gradual progression of visual changes from diplopia to illusions and finally to hallucinations occurred with similar frequency.

The visual phenomena were commonly described as fog, mist, or smoke issuing from under doors or from the walls. Geometric designs of great complexity were seen by an artist and confirmed in a kind of *folie à deux* by a younger subject whom he had treated paternalistically since the inception of the experiment. Periods of splitting of consciousness were reported, characterized by the feeling of being in two places at once. These hypnagogic or dreamlike states were responsible for inappropriate responses or behavior for which the subject was amnesic.

Body image changes included feelings of numbness and depersonalization. The sensation of being detached and observing one's own body from a distance was reported by some subjects. The experience of the "hat illusion" was reported by every participant in the project.

Of interest was the initial veridical questioning of hallucinations by subjects, followed by acceptance and belief as they continued. Although most subjects became paranoid, systematized delusions occurred in only one man who had residues of paranoid thinking up to one month.

The autonomic studies of Ax and Luby revealed a progressive decline in activation or level of arousal as determined by palmar

¹ Read at the 117th annual meeting of The American Psychiatric Association, Chicago, Ill., May 8-12, 1961.

² From The Lafayette Clinic and Wayne State University, Detroit, Mich.

conductance, galvanic skin response, frontalis muscle tension, and the response of diastolic blood pressure to a pain stimulus (8). These variables fell significantly throughout the experiment until at 100 hours there appeared to be profound central sympathetic fatigue. This was particularly manifest when diastolic blood pressure paradoxically fell in response to a pain stimulus.

Biologic energy production was studied by measuring the specific activity of adenosine triphosphate (ATP) in red cells together with levels of the total adenine phosphates at various times during the course of the sleep deprivation. High energy phosphate formation as measured by the specific activity of ATP in the subjects' own erythrocytes was stimulated in the initial phase of sleep deprivation. Levels of the adenine phosphates paradoxically fell and remained low throughout the experiment. Between 90 and 120 hours the mechanisms associated with energy production began to fail and ATP specific activity dropped precipitously. At this time a substance was elaborated in the serum of sleep-deprived subjects which inhibited succinic oxidase activity in rat liver homogenates. Inasmuch as the serum had been dialyzed, this substance was probably a protein or a polypeptide, but no efforts have as yet been made to characterize or isolate it.

Motor performance tasks were correlated with depletion of high energy phosphorylation and diminished central sympathetic reactivity. Between 80 and 100 hours subjects were no longer able to dissipate work inhibition with brief rest, suggesting severe impairment of energy restorative mechanisms. The number of "lapses" or periods of no response to the testing situation reached a peak at this time.

The psychopathology and the performance decrements on psychological tests associated with sleep deprivation were interpreted within the framework of the "lapse hypothesis" promulgated by Williams, Lubin, and Goodnow(5). A "lapse" can be defined as a period of no response in which external sensory input is cut off and internal input is attended to presumably because the subject is drowsing. Lapses reach their peak intensity and frequency when phosphate

esterification becomes depleted and central sympathetic responsivity is considerably diminished.

It can be hypothesized that attention to external sensory input requires greater sympathetic arousal and mobilization of energy resources than attention to internal stimuli, possibly because the external source necessitates more active and effortful scanning and orientation reactions. The sleep-deprived subject, with his energy resources depleted, will then be likely to react predominantly to these internal stimulus cues, especially during periods where "lapses" or brief periods of drowsiness occur. The subject's behavior at these times can be compared with other conditions in which there is faulty filtering of input and inability to narrow attention or to maintain repression. Moving from one frame of reference to another is admittedly hazardous, but the speculation can be made that maintenance of attention, reticular and sympathetic arousal, and mobilization of high energy phosphorylation are closely interrelated phenomena.

Cohen and Frohman(9), attempting to correlate certain performance tasks with energy production, discovered that there was a significant relationship between increased ATP specific activity in response to insulin and the ability to perform a work output task demanding sustained attention. This relationship was present in both non-psychotic control subjects and in schizophrenic patients. Callaway and Dembo(10) coined the phrase "narrowing of attention" to describe the filtering out of peripheral stimuli (peripheral in terms of time, space, or meaning) and correlated this with the level of central sympathetic activity. Thus ability to mobilize ATP with associated sympathetic arousal may be crucial for sustaining attention and filtering sensory input.

How can these changes in energy production occurring in the sleep deprivation model be related to schizophrenia? Frohman and Gottlieb(11, 12, 13, 14) have reported impairment in the ability of chronic schizophrenic patients to increase ATP turnover and to shift from the synthetic hexose monophosphate shunt to the high energy Emden-Meyerhof scheme of metabolism in adaptive response to an insulin stressor.

The origins of such a defect are obscure but it may be the result of sustained, overwhelming anxiety, a genetically determined enzyme lesion, or inadequate exposure to stressors in childhood as a consequence of maternal overprotection. The last interpretation is suggested by the work of Beckett, *et al.* (15), showing a relationship between the severity of a defect in intracellular energy transfer mechanisms and symptomatology, chronicity, premorbid characteristics, and early parent-child relations.

The presence of an inhibitory substance in the serum of sleep-deprived subjects is of concern because of present interest in a "plasma factor" in schizophrenia. Frohman (16) has isolated an alpha globulin from the plasma of schizophrenic patients which when incubated with chicken erythrocytes shifts intermediary carbohydrate metabolism to more anaerobic mechanisms.

It appears most probable that the phenomena of sleep deprivation are associated with or result from a progressive failure in energy production and central sympathetic responsivity. Although this failure may result from depletion of phosphate esterification, the neurohumoral transmitter substances may be similarly diminished. The presence of a factor in the serum which depresses succinic oxidase suggests that this substance may play an important role.

The question must be asked whether the factor found in the serum of sleep-deprived subjects is related to the active fraction isolated from plasma of chronic schizophrenic patients. The question must also be asked whether the temporary failure in the mechanisms of energy production associated with the stress of sleep deprivation would become irreversible, as seen in the chronic schizophrenic patient, if the sleep-deprived period were extended.

SENSORY ISOLATION

Leaving the questions raised by our studies of sleep deprivation, let us now examine the phenomena produced by sensory isolation and concern ourselves with its possible contribution to an understanding of mechanisms in schizophrenia. When the normal level and quality of sensory influx is drastically reduced or made monotonous in the case of otherwise awake, healthy per-

sons, behavior tends to become disorganized. The McGill group placed volunteer subjects in an extremely monotonous setting for periods ranging from several hours to 6 days. They observed progressive intellectual deterioration and other effects including vivid visual hallucinations (17). Comparable results were reported by Lilly with subjects who were isolated while immersed in a tank of water for 2 to 3 hours (18). Wexler, *et al.*, obtained similar findings with poliomyelitis patients and normal subjects restricted for 8 hours in a tank-type respirator (19).

In general, the more common effects of sensory isolation occur in a fairly consistent sequence. Anxiety and intense discomfort are reported, mild depersonalization and derealization are experienced, thinking becomes less controlled and more reverie-like, and finally visual, kinesthetic, and tactile illusions and hallucinations may occur. Auditory experiences are much less frequent.

In our own laboratories, the hallucinatory perceptions obtained in one hour of isolation were regarded as resulting largely from increased sensitivity to residual stimuli which ultimately generated the fabrication of events in a situation providing only minimal opportunities to test reality. In normal subjects, anxiety and discomfort were typical, but little change in thinking was seen (20).

We interpret these effects of sensory isolation in control subjects in terms of the discrepancy between alert and active reception interpretation systems on the one hand and the abnormally reduced external input on the other. In brief, the state of the intact, awake organism is normally accommodated to a characteristic range of dynamic input. When this input is drastically reduced while reception and interpretation systems are still functioning at their characteristic levels, tensions will accumulate which cannot be adequately discharged in the typical sensory isolation experiment because of the imposed restrictions on movement and activity. Hence, anxiety and discomfort result. Also, residual but ordinarily inconsequential background cues from without or from within the organism are likely to be hypercathected and provide the basis

for illusory and hallucinatory perception.

We have studied the effects of sensory isolation in chronic schizophrenic subjects (20). The most distinctive finding was that the psychotic subjects in poor reality contact showed the *least* discomfort and the most affectively positive reactions to the procedure. They regarded the experience as pleasant and comfortable, and retained calm composure throughout the hour. This was in marked contrast to the reactions of the nonpsychotic subjects as described above. While the schizophrenic subjects did report some hallucinatory perceptions, these were not different from their usual (non-isolation) responses. These results are substantially similar to those reported by Harris for schizophrenic patients (21). Reduction of sensory input did not exacerbate schizophrenic pathology, and in some cases it had an ameliorating effect.

If our interpretation of sensory isolation phenomena is valid, the inference can be drawn that the cognitive organization of schizophrenic subjects is characteristically "geared down" so that they experience difficulty in the central accommodation of normal sensory inflow. The isolation setting, then, may be one which presents to the schizophrenic subject a more balanced relation between input load and reception interpretation capacity. Schizophrenic withdrawal may represent an attempt by the patient to reduce input overload, resulting in a form of learned self-imposed sensory isolation.

PSYCHOTOMIMETIC DRUGS

We turn now to a pharmacological technique in which body feedback mechanisms are apparently disrupted while the subject remains exposed to normal sensory loading. The drug used, Sernyl, (1-(1-phenylcyclohexyl) piperidine monohydrochloride) was originally developed as a preanesthetic and tranquilizing agent. It apparently depressed central integrating mechanisms involving various sensory modalities such as touch, pain and proprioception. Our initial studies with it were prompted by a desire to observe the effects of "interoceptive" sensory deprivation resulting from administration of the drug at dosage levels which permitted

the subject to remain awake and communicate.

The psychopathological effects of Sernyl have been described by Luby, *et al.* (22). When given intravenously to control subjects at a dose level of 0.1 mg./kg. the drug produced a predictable series of changes mimicking the primary symptoms of schizophrenia. Initially alteration of body image occurred with a loss of body boundaries and a profound sense of unreality. Then feelings of estrangement and loneliness ensued, sometimes associated with an intensification of dependency needs and attachment to the observer. Progressive disorganization of thought, inability to maintain a set, loss of goal ideas, impairment of abstract thinking, blocking, neologizing, negativism, and hostility all followed. Some subjects became catatonic and many had dream-like experiences in which they felt as though they were in a different setting at a different time. Genuine hallucinations were not characteristic effects of the drug.

Since distortions of body image and depersonalization were universal reactions to Sernyl and occurred just prior to the other deficits in thinking and affect, it was hypothesized that the effect of the drug was mediated through the reduction of proprioceptive feedback or impairment of the central integration and interpretation of input from this sensory modality. Experiments were next set up by Rosenbaum, *et al.*, to provide data with respect to this hypothesis, employing performance tasks which were considered to depend on an intact proprioceptive feedback system (23). These included measures of attention (reaction time), motor function (rotary pursuit learning), and proprioceptive acuity (weight discrimination). The effects of Sernyl on the tasks were compared with those of lysergic acid diethylamide (LSD) and amobarbital. In addition, a criterion group of chronic schizophrenic patients was tested without drugs in an attempt to find how closely the performance of control subjects under each of the drugs approximated that of schizophrenic patients. The results clearly demonstrated that Sernyl produced severe impairments beyond those attributable to sedation (as seen by comparison with amobarbital) or to some general psy-

chotomimetic factor (as indicated by comparison with LSD). Also, Sernyl was the only drug to produce the level and pattern of deficits shown by the criterion group of schizophrenic subjects. The same results were found by Cohen, *et al.*, with tasks involving symbolic and sequential thinking (24).

The inference was drawn that Sernyl results in schizophrenic-like primary attention and cognition deficits, while LSD simulates secondary phenomena (*e.g.*, hallucinations). The findings were regarded as consistent with the hypothesis of a disturbance in proprioceptive feedback mechanisms in both the Sernyl state and in chronic schizophrenia.

With the hypothesis in mind that Sernyl acts through a disruption in body feedback systems, and that such a disturbance already exists in schizophrenia, it was decided to observe the effects of Sernyl in schizophrenic subjects. The results were quite vivid. Sernyl produced profoundly disorganized regressive states in these patients. Their thought disorders were greatly intensified and considerable affective expression was stimulated. It was as though the acute, agitated phase of the illness had been reinstated. Chronic patients generally became more assertive, hostile, and unmanageable. Unexpectedly, the behavioral changes persisted from 4 to 6 weeks after Sernyl injection in these patients.

Since the administration of Sernyl accentuated schizophrenic symptoms, we concluded that the drug touched upon some fundamental aspect of the disease. Tentatively, we believe this feature to involve central integration of body input or a disturbance in the proprioceptive feedback system.

Having observed that chronic schizophrenic patients tolerated sensory isolation with so much less tension and discomfort than control subjects, and in view of the possible intimate relation between the Sernyl state and schizophrenia, it was considered instructive to observe the reactions of Sernyl injected control subjects under sensory isolation conditions. The data consisted of immediate observations of the subjects and their retrospective accounts of the experience. The results reported by

Cohen, *et al.* (25), indicated that the manifest psychotomimetic phenomena usually produced by Sernyl under non-isolation conditions were markedly attenuated under isolation. The subjects were not asleep and were able to report on their experiences, at least retrospectively, as "nothingness" and "total emptiness." The state was analogized with "death." Compared to non-isolation experiences with the drug, the subjects felt calm and self-controlled.

Our conclusion was that the usual psychotomimetic effects of Sernyl required exteroceptive inputs for their arousal. It occurred to us that the Sernyl engendered state resembled schizophrenia to the extent that subjects under the drug tolerated sensory isolation in a manner similar to that reported by Harris and Cohen, *et al.*, as characteristic of schizophrenic patients. Perhaps both the model psychosis of Sernyl and the clinical psychosis of schizophrenia produce a disturbance in the capacity of the organism to filter and interpret a normal sensory input load. This handicap results in generalized aversion to the complex and dynamic influx that is characteristically provided by the normal sensory environment.

We do not believe that the disturbance is at a receptor or spinal cord site, as evidenced by the fact that the patellar reflex is enhanced (22). A more central system responsible for the integration of exteroceptive with body feedback inputs is probably operative, perhaps at a thalamic or cortical level (26). The appropriate adaptive accommodation of exteroceptive inputs requires that the central system be intact. When it is not intact, the organism will seek and prefer more simplified and monotonous environments, and will withdraw from those that are more complex and changing.

DISCUSSION AND SUMMARY

All model psychoses may be conceptualized as resulting from disruption in the central processing or from interference with the normal sensory influx from body or distance receptors. The experimental findings of the effects of sleep deprivation, sensory isolation, drugs, and a combination of drugs and sensory isolation in control and schizophrenic subjects warrants the devel-

opment of a hypothesis within this context to explain some of the mechanisms responsible for schizophrenic behavior. Such a hypothesis must be operational in the sense that its elements must be susceptible to experimental verification.

Evidence has been presented that sleep deprivation is at first accompanied by an adaptive high biologic energy turnover, but that finally a point is reached after several days when energy producing mechanisms decompensate. Moreover, it appears possible that a "stressor substance" develops in the serum of these subjects which may be responsible for the progressive failure of the mechanism of energy turnover.

While the failure in the mechanism of adaptation for supplying the needed biologic energy for sleep-deprived subjects is reversible, one may ponder about its relationship to the permanently disturbed mechanisms controlling the formation and utilization of biologic energy that characterizes the chronic schizophrenic patient. Two questions are pertinent. Do traumatic sociopsychological experiences at an early period of life when these biochemical mechanisms are in the process of maturation limit their adaptive responsivity? Conversely, does inadequate exposure to normal sociopsychologic stressors at a critical maturational period inhibit their development?

How does the succinic oxidase inhibiting "stressor" substance in the serum of persons deprived of sleep relate to the alpha globulin in the serum of schizophrenic patients, which shifts intermediary carbohydrate metabolism to more anaerobic mechanisms? Only further study will tell, but it is conceivable that they are related.

Nevertheless, the alpha globulin isolated by Frohman and others from the plasma of schizophrenic patients apparently affects neutral transmission centrally. It alters the behavior of monkeys and rats and according to Marrazzi inhibits transcallosal synaptic conduction (27, 28). This need not necessarily imply ease of passage through blood brain barrier because the protein may act by increasing permeability or as a carrier system for a smaller molecule. Our studies on model psychoses can, perhaps, contribute to a hypothesis concerning the mechanism of action of this substance.

Meaningful exteroceptive input is necessary for normal psychological functioning, but apparently induces aversive responses in schizophrenic patients. This suggests that the central stimulus filtering and interpretation capacity of these patients is diminished. Conceivably the defect may be similar to that produced by Sernyl and involve the disruption or reduction of body input transmission and integration.

In Kubie's parlance, when the subject's image of himself, "the I," is destroyed, the ability to assess external reality or the "not I" is lost (29). As Federn suggested, depersonalization may be the core of schizophrenia (30), and disturbed body input transmission or integration may be its basis. In our hypothesis such disturbed neural integration in schizophrenia might result either from the presence of an inhibitor substance or from a defect in energy production.

Analogous situations in the animal can be produced by psychotomimetic drugs such as Sernyl or by lesions in lateral mid-brain involving tracts mediating touch, proprioception, and pain. Sernyl has been shown by Lees to be an uncoupling agent (31). It may thus reduce available energy stores, although admittedly other uncoupling drugs do not produce psychotomimetic effects. That Sernyl has profound action on central reception and integration of body input is evidenced by the work of Van Meter, *et al.* (32), and Domino (26). At the cortical level both axosomatic and axodendritic synapses are partially blocked by the drug. There is also evidence for depression of the diffuse thalamic projection system.

Recent work on destruction of lemniscal pathways in the cat by Sprague, Chambers, and Stellar might lend additional support to our hypothesis. When the sensory afferent systems mediating proprioception, pain, and touch in these animals were cut, severe behavioral changes occurred. The cat was rendered incapable of attending to or making adaptive responses to relevant stimuli associated with eating, sexuality, or defense. Emotionality was diminished and the cats seemed flat and automaton-like. At times they appeared to be hallucinating (33).

These disrupted body input mechanisms

may be considered as responsible for the disturbances in psychological functioning of the schizophrenic patient. This aspect of our hypothesis could be easily subjected to direct test if the human brain were readily available for experimentation and study. Being realistic, however, we must have recourse to analogous study in animals to increase our knowledge. This prolongs and complicates the challenge.

CLINICAL NOTES

(The Clinical Notes report the findings of the authors and do not necessarily represent the opinions of the Journal.)

A COMPARISON OF A RECENTLY INTRODUCED PHENOTHIAZINE DERIVATIVE (MDS 92) AND A PLACEBO IN CHRONICALLY ILL MENTAL PATIENTS

A. BARRON, M.D., BARBARA BECKERING, R.N., LESTER H. RUDY, M.D.,
AND JACKSON A. SMITH, M.D.¹

Thirty chronically disturbed female patients on a continuous treatment ward in a state hospital were included in the study. The usual behavior pattern of these patients was known. Their ages ranged from 20 to 64 years. Average length of hospitalization was 11.8 years. The diagnoses were: schizophrenic reactions, 25, and involutional psychotic reaction, 5. The drug used was MDS 92 (hydroxyethyl piperazine propyl phenothiazine maleate).

METHOD

The project was carried out as a "double-blind" study with a cross over. The 30 patients were divided randomly into subgroups A and B. One group received MDS 92 and the other the placebo. The active preparation was prescribed in increasing doses every 10 days (see Table 1). At the end of 30 days a "cross over" was carried out with the group which previously received the inactive compound receiving the drug. The active medication and the placebo were prepared in identical capsules.

TABLE 1
Dosage and Administration

	MDS 92	PLACEBO
1st to 10th day	30 mg. daily	—
11th to 20th day	50 mg. daily	—
21st to 30th day	100 mg. daily	—

¹ Staff of the Illinois State Psychiatric Institute, Chicago, Ill.

This study was done at the Chicago State Hospital and the cooperation of Dr. H. Maltz, Superintendent, is appreciated.

Appreciation is expressed to Wyeth Laboratories, Randor, Pa., for the supplies of MDS 92.

Neither the patients nor the observer were aware whether the drug or the placebo were being given.

Evaluation of Behavior Change. A research nurse who was an experienced observer used standardized evaluation forms previously described² to record any change that was seen in the patient's behavior. She made a complete control evaluation of each patient immediately prior to the start of the project and at the end of each month, in addition to weekly progress notes. A psychiatrist worked with the research nurse and evaluated side effects from the drugs. Complete blood counts and liver function tests (alkaline phosphatase and thymol turbidity) were done weekly throughout the length of the study.

RESULTS

The patient's clinical response during the study was tabulated as worse, no change, slightly improved, moderately improved and markedly improved. The final results are shown in Table 2.

TABLE 2

	Worse	No Change	Slightly Improved	Moderately Improved	Markedly Improved
MDS 92	1	11	6	11	1
Placebo	17	12	1	0	0

The criteria for evaluation were the observed decrease or increase in the following variables of behavior: overt hostility, tension, agitation, attempts to communicate,

² Smith, Jackson A., Christian, Dorothy, Mansfield, Elaine, and Figeredo, Alfredo: *Am. J. Psychiat.*, 116: 392, Nov. 1959.

cooperation, friendliness, attention span and alertness, interest in personal appearance, mannerisms, participation in activities, or a change in delusions and hallucinations. Patients considered slightly improved showed favorable change in 2 or 3 variables; those moderately improved showed this change in at least 4 or 5 variables; marked improvement reflected change in 6 or more of the listed variables; a patient was considered worse if an unfavorable change was noted in 2 or more of the variables.

There was a consistent variation of patients' weight during the 2-month study depending on whether they were on the active preparation or the placebo. Eighteen patients gained from $\frac{1}{2}$ to 10 pounds (average $4\frac{1}{2}$) while receiving MDS 92; and 16 of them lost 1 to 12 pounds (average $3\frac{1}{2}$) during the time they received placebo.

Although these patients showed variations in their weight from time to time, these differences were more consistent and

more marked than the incidental changes usually seen.

SIDE EFFECTS

Several mild side effects were observed during the administration of MDS 92. However, they were easily controlled by reducing the dose or with antiparkinsonian medication. It was not necessary to discontinue the medication in any case during the study. The side effects observed are shown in Table 3.

THE PREDICTION OF RESPONSE TO TRANLYCYPROMINE PLUS TRIFLUOPERAZINE BY THE MMPI¹

EDWARD S. SULZER, PH.D., AND BURTRUM C. SCHIELE, M.D.²

The clinical experiences of several psychiatrists in this area, as well as the experiences of other physicians reported in this Journal (1-6), have indicated that in combination, tranlycypromine (Parnate)³ plus trifluoperazine (Stelazine)⁴ have positive effects in the treatment of certain psychiatric patients. Claims of success have been made especially for patients described as chronically depressed and as having numerous neurotic characteristics. While many of these patients are reported to show marked improvement on the combined drug schedule, other patients reveal little or no change. Therefore, it would appear to be of

considerable utility if we might discern in advance which particular patient or patients would be most likely to benefit from this drug combination.

The Minnesota Multiphasic Personality Inventory (MMPI) (7) is a psychological instrument that has been used widely in assessment procedures and in the evaluation of psychiatric treatments (8-11). In an effort to determine the potential predictive utility of the MMPI, we have gathered a sample of 31 cases in which the psychiatrist has reported substantial clinical improvement following a period of tranlycypromine and trifluoperazine ingestion. From the same psychiatrists, we have gathered a sample of 21 cases in which little or no improvement was reported. All 52 patients received the medication for a period of no fewer than 5 days and had been given the MMPI prior to the drug treatment.

The 52 patients were all described as

¹ This investigation was supported, in part, by a PHS research grant, MYP-5106, from the National Institute of Mental Health, Public Health Service.

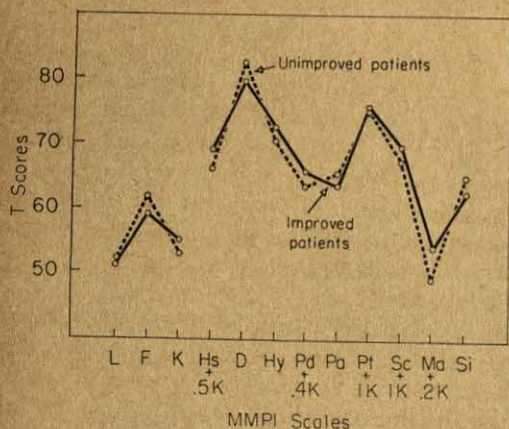

² Respectively, Instructor and Professor, Dept. of Psychiatry and Neurology, University of Minnesota Medical School.

³ Smith Kline & French.

⁴ Smith Kline & French.

presenting the characteristics cited above, and therefore being the most appropriate group for the treatment. However, variables such as age, sex, and other clinical characteristics could not be readily controlled. We simply requested that the pre-drug MMPI be furnished us along with the psychiatrist's opinion as to the presence or absence of substantial clinical improvement in behavior.

Mean MMPI Profiles for Improved and Unimproved Patient Groups

The mean T scores for the 3 validity scales and the 9 most commonly used clinical scales on the MMPI were computed separately for the two groups and the results are reported in the figure with the appropriate K corrections. As may be seen, the mean pre-drug profiles are astonishingly similar. Statistically, no difference was obtained in any scale comparison at the .05 level of significance for the arithmetic means.

The findings reported here are such that

we cannot demonstrate the utility of the MMPI in differentiating in advance "good" versus "poor" responders to the combined medication. However, one should bear in mind that many significant variables were left uncontrolled. On the other hand, our results are in accord with the findings of many other investigators when it comes to the prediction of response for a particular treatment in psychiatry. We appear to have little in the way of methods or techniques that permit us to have a substantial amount of confidence in predicting outcomes of treatment. Nevertheless, we should continue clinical investigations such as reported here.

COMPARISON OF BUTYRILPERAZINE AND TRIFLUOPERAZINE IN CHRONIC SCHIZOPHRENIC SUBJECTS

WILLIAM MANDEL, M.D., AND PHILIP EVANS, M.D.¹

We have conducted a comparative, controlled, clinical trial of butyrylperazine and trifluoperazine,² phenothiazines of the piperazine series, in chronic schizophrenic

patients. This was a double-blind, cross-over study with fixed dosage regimens and with two placebo intervals.³

¹ Respectively, Chief of Research, and Staff Psychiatrist, Napa State Hospital, Napa, Calif.

² Denber, H. C. B., Ross, E., and Rajotte, P. : *Am. J. Psychiat.*, 117 : 1119, June 1961.

³ Butyrylperazine (Riker 595), trifluoperazine (Stelazine) and matching placebos were made available by Riker Laboratories, Inc., Northridge, Calif.

MATERIALS AND METHODS

The patients were 44 psychotic hospitalized males with the diagnosis of chronic schizophrenic reaction. The selection criteria were: 1) proper diagnosis; 2) age below 60; 3) absence of organic disease, and 4) discharge not expected within 6 months.

The age range was 18 to 58 years, the mean being 40; the length of hospitalization ranged from 1 to 33 years, the mean being 8.3.

The dosage of butyrylperazine was 10 mg. t.i.d. and of trifluoperazine, 8 mg. t.i.d. Patients were randomly assigned to medication which was so prepared that one bottle contained medication for 2 weeks; six bottles for each patient being sufficient for 3 months. The unknown was administered for 1 month and was followed by placebo for 2 weeks. The second unknown (cross over) was then given for 1 month and followed by placebo for 2 weeks.

All patients were studied simultaneously. Progress notes and a revised MACC behavioral rating scale were performed bi-weekly. These ratings were done by the same person on the same patients. A global rating of "none, slight, moderate or marked improvement" in behavior and content from prestudy status, and a global rating of "none, slight, moderate or marked" change from normal were made bi-weekly. These ratings were performed independently by 3 observers. A final global rating of "none, slight, moderate or marked" improvement was based upon all available data. If a final evaluation was deemed to fall between 2 ratings, it was placed in the lower rating.

RESULTS

The improvement after 4 weeks is presented in Table 1. There was no significant difference between the drugs. The second evaluation, after 10 weeks, is presented in Table 2. Again, there was no significant difference between the drugs.

Butyrylperazine was more effective than

TABLE 1
Global Rating of Improvement—After 4 Weeks

	NONE	SLIGHT	MODERATE	MARKED
Butyrylperazine	8(39%)	8(38%)	2(10%)	3(14%)
Trifluoperazine	6(28%)	7(33%)	4(20%)	3(14%)

TABLE 2
Global Rating of Improvement—After 10 Weeks

	NONE	SLIGHT	MODERATE	MARKED
Butyrylperazine	5(23%)	7(32%)	4(18%)	6(27%)
Trifluoperazine	6(28%)	6(28%)	5(24%)	4(20%)

trifluoperazine in 14 patients; trifluoperazine was superior to butyrylperazine in 13 patients, and both were equally effective or ineffective in 15 patients. Whether butyrylperazine or trifluoperazine was given first did not affect the response to either drug.

No extrapyramidal reactions occurred with either drug in 15 patients. Nineteen patients developed extrapyramidal reaction with both drugs; 5 developed reactions only with butyrylperazine, and 5 only with trifluoperazine. There was no significant difference in the incidence of extrapyramidal reactions between the drugs.

Treatment was not completed in 4 patients. One refused medication, 2 went on unauthorized leave, and medication was discontinued in the fourth because of extrapyramidal reactions.

DISCUSSION

There was no significant difference between the drugs in effectiveness or incidence of side reactions. Some patients responded more rapidly and effectively to one drug than to the other. Improvement which occurred during the first month tended to be maintained or improved further following the crossover. We were unable to determine factors which would help in preselecting patients who responded most effectively to either drug.

SUMMARY

Butyrylperazine, a new phenothiazine of the piperazine series, was compared with trifluoperazine in a 3-month study involving 44 chronic schizophrenic patients. The study employed a double-blind, cross over design using a fixed dosage regimen of both drugs. A 2-week placebo interval was used prior to the cross over and at the completion of the study.

There were no significant differences in therapeutic effectiveness or incidence of side reactions between the drugs. Similarities between the drugs were greater than differences.

FLUPHENAZINE IN CHRONIC REFRACTORY SCHIZOPHRENICS

N. E. STRATAS, M.D.¹

A group of 20 chronic schizophrenics who were only marginally controlled were selected for treatment with fluphenazine (Prolixin) in view of fairly good results reported previously with this drug in these groups (1, 2). They were all females on one of the chronic wards of the Dorothea Dix Hospital and were characterized by episodes of severe uncooperativeness, neglect of personal appearance, posturing, delusions, hallucinations and withdrawal. They ranged in age from 27 to 55, and their histories indicated that in all these patients onset of illness had been gradual, while duration of illness ranged from 3 months to 28 years, the average being slightly over 12 years. Previous treatment had encompassed everything imaginable and all were currently receiving other phenothiazines and particularly chlorpromazine (Thorazine) and prochlorperazine (Compazine).

All psychopharmacology was discontinued and fluphenazine, given orally in tablet form, was started at 1 mgm. b.i.d. The dose was raised as felt necessary by the ward physician to a maximum of 15 mgm. t.i.d., the average dose being 5-10 mgm. b.i.d. Treatment lasted for 4 months in most cases.

The patients were evaluated weekly and separately by the ward nurse, the ward physician, and the supervising psychiatrist. The evaluations were made in reference to mood, behavior, attitude, hallucinations

and delusions on progressive comparative charts.

RESULTS

Grossly, the results were that none of the patients showed very much improvement; 4 were considered slightly improved, 7 became worse, and 1 was unchanged. Without going into the particular details of each characteristic evaluated, it was particularly noted that most aggravated were behavior and attitude, as the majority of the group became more unmanageable and uncooperative. In contrast, however, the hallucinatory and delusional material decreased in 6 of the group. None of them improved to the extent that transfer to a better ward was feasible.

Extrapyramidal signs were the most frequent side effects, occurring in 9 patients, and were controlled either by reducing the dose or more usually by adding trihexyphenidyl HCl (Artane). Another prominent side effect was hypotension, and in 3 cases the drug had to be discontinued.

CONCLUSIONS

In light of these findings we can only conclude that fluphenazine is not of any material value over any of the other phenothiazines in the treatment of the chronic refractory schizophrenics.

OLFACTORY CHANGES IN SCHIZOPHRENIA

A. HOFFER,¹ AND H. OSMOND²

The experiential, phenomenal, or self world of psychiatric patients, all of which is included in Von Uexkull's (6) useful term "Umwelt," has received surprisingly little

systematic attention. Patients frequently have major perceptual changes which can be easily elicited, but these are seldom described or recorded by their doctors. When questioned directly these patients have little hesitation in giving direct answers. Indeed, schizophrenic patients seem to find it easier

¹ Director, Psychiatric Research Unit, University Hospital, Saskatoon, Sask.

² Onet Cottage, Milford, Surrey, England.

to talk about their present "Umwelt" which they themselves often find troubling and disturbing, than about their feelings regarding events long past which their psychiatrists often consider to be interesting. Perhaps people who do not themselves have perceptual difficulties and who do not remember those which they may have had in their youth cannot imagine how distressing such changes must be. It is not easy for those with ordinary vision to imagine with any degree of accuracy the world of, e.g., a red-green colour-blind person, yet this is a comparatively simple perceptual change affecting about 1 man in 25. William James gives an interesting example of a good visual-imager asking a friend who had poor imagery to explain how he could think or remember. Once one has experienced such perceptual anomalies oneself it is much easier to imagine their effects upon others. One of the uses of mescaline, LSD 25, psilocybin or the more insidious substances such as adrenochrome is to allow those who work with the mentally ill to have at least a glimpse of a psychotic-like experience.

Since 1950 we have taken and observed the effects of most of the known psychotomimetics and have examined autobiographies of a considerable number of patients, many of whom suffered from a variety of schizophrenic illnesses. In consequence we became increasingly aware that perceptual changes occur in schizophrenia far more often than has generally been supposed.

Bleuler's dictum that perceptual changes do not occur in schizophrenia has rarely been challenged directly. It has had to be ignored. Bleuler's idea was that there were primary disturbances of association from which all other changes originated. Kraepelin was not slow to point out that it was impossible to show that changes of association had any particular primacy. It has indeed become evident that perceptual changes are as useful in detecting early schizophrenia as Bleuler's allegedly primary disturbances of association. From their extensive follow-up studies Lewis and Pietrowski(3) selected 10 factors whose presence showed that patients had schizophrenia long before a clinical diagnosis of this illness could be made. Five of those

factors are concerned with perceptual changes.

Rubert, Hollander and Mehrhof(5) found that schizophrenic patients often have olfactory hallucinations. They were just as frequent as auditory hallucinations. They occurred in 19 of 24 acute cases and in 11 of 12 chronic ones. Unpleasant smells were three times as common as pleasant ones. We are not convinced that these olfactory changes should all be lumped together as hallucinations. They might for instance be illusions, or even more likely an increased acuity of the sense of smell for odours which are always there, but not always noticed. The extent to which a smell seems pleasant depends probably upon the concentration of molecules striking the nasal mucosa. Many smells become extremely unpleasant if too concentrated, although not distasteful when weaker; for instance, a mild human body odour may be attractive and even exciting, but in excess it is usually thought to be offensive. At least some of the unpleasant odours of which patients complain may therefore be accounted for by an increased sensitivity (decreased threshold) to odour.

In March 1960 we had a schizophrenic patient who described many perceptual changes but few of them were olfactory. He was treated with 3 gm. of nicotinic acid daily. In October of the same year he returned for a follow-up. He stated that he was well, his wife thought that he was well and he seemed to be well when examined. He was running his business successfully and had no difficulty with his family, friends and acquaintances. However, he had one complaint—his dairy barn he said smelled very bad. He had done everything he could to reduce the odour, including almost excessive cleanliness, air conditioning, deodorizers, etc. It was suggested to him that he might now have some increased sensitivity to smell. He looked startled when we said this and added that when he had been ill and his barn had been neglected, his wife had complained of the stench in it, although he had not then been aware of this. It seems possible that his other perceptual anomalies had prevented him noticing this smell. At least this explanation satisfied him and he continued his recovery with no more difficulty.

Weckowicz(7), Weckowicz, and Hall(8),

Weckowicz, Sommer, and Hall(9), Crooke (1) and Raush(4) have shown that schizophrenic patients had many perceptual anomalies and they suggested clinical tests could be based upon these changes.

Hoffer and Osmond(2) examined the relationship between perceptual changes reported by patients and the presence of unidentified substances (US) in their urine. These were changes reported in the clinical records of the patients. Eighteen of 27 schizophrenic patients with US in their urine had perceptual changes. Only 2 of 11 patients without US had these changes. ($P < .05$). Five of 13 non-schizophrenic patients with US in their urine had perceptual changes, while only 5 of 35 without US had these changes ($P < .05$). For all patients the following distribution was found (Table IX in(2)).

	US PRESENT	US ABSENT
Changes present	23	7
Changes absent	17	39
Chi. Sq.=14 $P < .001$		

Of 40 patients with US present, perceptual changes were present in over 55%, while of 46 without US these changes were present in about 15%.

Using our card-sorting test, in which many cards bear questions dealing with perceptual changes, we found that schizophrenics, patients with toxic psychoses and subjects who had taken LSD 25 placed many more cards in the "true" category

than those with other diagnoses and normal persons. The questions bearing on olfactory perception are :

- #57—Things smell very funny now
- #58—My body odor is much more noticeable than it once was
- #59—My body odor is much more unpleasant now
- #60—I sweat much more now than I used to
- #61—I can no longer smell perfume as well as I used to
- #62—Foods smell funny now
- #129—Other people smell strange

The proportion of patients placing these cards in the box marked "true" is shown in Table 1.

Normal subjects have very few perceptual changes, which of course includes olfactory complaints as well. Non-schizophrenic patients complained of sweating more than they had before they were ill but only 16 of 123 stated that their body odour was more unpleasant. Acute schizophrenics also selected the same three cards (58, 59 and 60) but 9 of 34 claimed their body odour was more unpleasant. (chi sq.=3.5 p 6.5.) Chronic schizophrenics however had many more complaints of a bizarre nature, i.e., that people and things smelled funny. The responses to card 57 are indicative of this.

CARD 57	TRUE	FALSE
Chronic schizophrenic	20	77
Non-schizophrenic	2	121
$X^2=100$		

TABLE 1
Incidence of Olfactory Perceptual Changes in Psychiatric Patients, Percent

N Card	GROUP			SCHIZOPHRENIC	
	NORMAL	NON SCHIZOPHRENIC	ACUTE	CHRONIC 1-10 YEARS	CHRONIC 11-20 YEARS
	100	123	34	63	34
57	0	2	6	18	27
58	0	20	27	16	36
59	0	13	27	20	30
60	1	49	60	27	24
61	1	5	12	19	33
62	0	8	18	17	24
129	0	2	3	25	21

If the amount of sweating is a measure of anxiety as it may well be, then acute schizophrenics were as anxious as non-schizophrenic patients but only about a quarter of the chronic cases had this complaint. This agrees with the clinical findings that chronic patients seem to have less anxiety. The incidence of olfactory changes using our test is somewhat less than that reported by Rupert, *et al.*, but their findings are corroborated.

Smell is a sense which in our Western culture at least has been neglected in recent years, yet olfactory percepts are very closely linked with affect, and in many persons they are extremely evocative of feeling. This suggests a possible explanation for the increasing apathy found in many schizophrenic patients. They are, in fact, being satiated with affect evoking stimuli, so that eventually indifference supervenes. We need very detailed information about the effect of disturbances in single perceptual features upon all perception, and the effect of a variety of simultaneous perceptual disturbances upon affect and thinking. We may then be able to understand better the mechanisms by which schizophrenic illnesses disrupt and distort relationships with other people. It may be that relatively small perceptual anomalies in particular modal-

ities, time sense for instance, may be far more upsetting than larger disturbances in other fields. We suggest that the neglect of these perceptual studies has deprived us of information which is essential if we are to have any deeper understanding of schizophrenia.

CLINICAL EVALUATION OF CARPHENAZINE AND PIPERACETAZINE IN PREVIOUSLY PLACEBO-TREATED CHRONIC SCHIZOPHRENICS

BESSIE CLAFFEY, M.D., LESTER H. MARGOLIS, M.D., AND
WILLIAM MANDEL, M.D.¹

This clinical trial was conducted to evaluate 2 new phenothiazines² in selected schizophrenic patients. One was of the piperazine (carphenazine) series(1), and the other of the piperidine (piperacetazine) series(2).

Eighty chronic schizophrenics were

chosen for this study : (44 women and 36 men, age range 29 to 54 years, mean age 43). They were hospitalized from 4 to 13 years, the mean being 8.6. Diagnoses : 32 paranoid, 13 catatonic, 3 hebephrenic, 32 undifferentiated schizophrenics.

Prior to this study, they were included in a 2-year controlled evaluation of 4 phenothiazines and placebos. During the first year, they received placebos under double-blind conditions for 4 months. There was no appreciable change in their condition. Thirty-nine patients were not given addi-

¹ Respectively, Staff Psychiatrist, Consultant, and Chief of Research, Napa State Hospital, Imola, Calif.

² Carphenazine (Proketazine) supplied by Wyeth Laboratories and piperacetazine (Quide) supplied by Pitman-Moore Company.

tional medication while 41 received low phenothiazine doses for 1 to 12 months; only 14 of these 41 patients showed improvement.

Forty-one patients received carphenazine and 39 received piperacetazine concurrently for 9 months. Dosage was started at 25 mg. daily and gradually increased until either intolerance from side-reactions or clinical improvement. The daily maintenance dosage of both drugs varied from 100 to 300 mg., most patients receiving from 150 to 250 mg. Patients who failed to improve or whose condition leveled off after 4 or more months were changed to other phenothiazines.

In addition to observations by personnel previously responsible for their care, the patients were seen biweekly by 2 consultants. Progress notes were made monthly. A global rating of "none, slight, moderate or marked" improvement in behavior and content from the start of the current study was made on the basis of all available data.

RESULTS

There was no statistically significant difference between the ratings of improvement for the 2 drugs (Table 1).

TABLE 1
Global Rating of Improvement

	NONE-SLIGHT	MODERATE	MARKED
Carphenazine	8(20%)	19(46%)	14(34%)
Piperacetazine	14(36%)	8(21%)	17(43%)

Extrapyramidal reactions occurred in 34 of the carphenazine-treated (83%) and in 26 of the piperacetazine-treated patients (67%). There was no statistically significant difference in incidence of these reactions. These reactions were controlled by antiparkinson drugs or by reduction of phenothiazine dosage.

After 4 or more months, medication was discontinued in 9 carphenazine and in 16 piperacetazine-treated patients, because they did not improve or leveled off after initial improvement. Two patients from

each group were transferred to other hospitals and one from each group went AWOL.

DISCUSSION

There were some qualitative differences between the drugs; carphenazine being more rapid in onset and more "stimulant" than piperacetazine. While there was no statistical significance in the numbers of patients treated, more instances of combined moderate to marked improvement and a greater frequency of extrapyramidal reactions occurred with carphenazine. The high incidence of extrapyramidal reactions may in part be attributed to our diagnostic criteria of including minor and transient clinical manifestations of extrapyramidal reactions.

In these schizophrenics who generally failed to improve during a previous 2-year treatment-observation period, 73% showed moderate or marked improvement. The degree of improvement can mainly be attributed to potent drugs given in adequate dosage for many months. In our experience, both drugs compare favorably with available phenothiazine derivatives.

SUMMARY

Carphenazine and piperacetazine, two new phenothiazines, were given to 80 chronic schizophrenic patients for 4 to 9 months. These patients had previously served as control subjects in a controlled drug evaluation and had not improved.

A global rating of moderate or marked improvement over their pre-study status was observed in 73% of the patients. There were no statistically significant differences between the drugs in degree of improvement or incidence of extrapyramidal reactions. Both drugs were considered effective phenothiazines for the chronic schizophrenic patient.

CASE REPORTS

JAUNDICE FOLLOWING THIORIDAZINE ADMINISTRATION

STANLEY L. BLOCK, M.D.¹

Since the introduction of chlorpromazine (Thorazine) in 1952, a variety of phenothiazines have been developed in an effort to provide greater potency of effect by weight or a modification of molecular structure in order to eliminate the side effects produced by the parent molecule. Thioridazine (Mellaril)² is a representative of the latter group of phenothiazines (1). Since the introduction of thioridazine in 1958, over 140 reports have appeared in the literature (2). All attest to the relative freedom from side effects. We report here a case of jaundice presumed to be the result of thioridazine administration. One previous instance has been reported (3).

The patient is a 79-year-old woman. The family reported increasing confusion and memory loss of 1 year's duration. She had become restless and agitated, seemed unaware of her memory loss, but complained of "nervousness" and loneliness. Examination revealed a cooperative woman who related easily; mood was undisturbed; vegetative signs normal; there was no evidence of bizarre ideation; she was oriented as to time and person but not to place and situation; recent memory and recall were impaired; simple calculations and judgment as measured by interpretation of proverbs showed no impairment.

Blood pressure was 150/80; pulse and respirations normal. Abnormal physical findings were: fundi showed moderate silver wiring and A-V nicking; marked bilateral hearing loss of a conduction type; the thorax was kyphotic; a hard, non-tender mass was palpated beneath the nipple of the left breast; neurological examination was negative.

Laboratory studies including complete blood count, urinalysis, blood urea nitrogen, serology, fasting blood sugar, cephalin flocculation, serum bilirubin and transaminase studies were

within normal limits. Roentgenograms of the chest and skull and an EKG were not significant.

A chronic brain syndrome secondary to arteriosclerosis was diagnosed. The breast mass was diagnosed as carcinoma and a simple mastectomy was performed. Pathological report indicated a scirrhous carcinoma of the breast. The patient made an uneventful surgical recovery. Her psychological disturbance was treated symptomatically with a combination of metrazol and nicotinic acid; thioridazine 25 mgm. q.i.d.; ferrous sulfate and chloral hydrate for night time sedation. She was maintained on this regime for 9 months at home, showed little restlessness, but progressive mental deterioration.

Periodic liver profiles and blood counts were normal. However, after 9 months the serum bilirubin was reported as 1.20 mgm. % and the transaminase was elevated. The thioridazine was promptly stopped. Within 2 weeks the liver studies reverted to normal. There was no clinical jaundice and the patient offered no complaints. The liver was neither enlarged nor tender.

DISCUSSION

A case of sub-clinical jaundice, presumed to be the result of thioridazine administration, is reported. The dosage was modest, but was given over a 9-month period. The length of administration rather than the size of the dose may be the important factor in producing the jaundice. Despite the relative safety of thioridazine, this case illustrates the possibility of jaundice developing with prolonged use of the drug and suggests the wisdom of periodic liver function tests as a precaution.

SCHIZOPHRENIA IN A PATIENT WITH GAUCHER'S DISEASE TREATED WITH MODIFIED ECT

JAMES F. SUESS, M.D.,¹ AND HARRY LITTLE, M.D.²

Several methods of modifying the anxiety and convulsive movements of ECT have been reported, including the use of succinylcholine chloride with sodium pentothal or the "petit mal technic" as described by Impastato, *et al.* (1-3). This report describes the use of succinylcholine modified ECT for a schizophrenic patient with Gaucher's disease in which pentothal was contraindicated because of liver involvement and "petit mal shock" was not used as it might precipitate a grand mal convulsion in a person with generalized bone pathology.

A 34-year-old man was admitted on July 21, 1960 with a 1-year history of syphilophobia, delusions of infecting his wife and children, burning sensation in his genitals, bizarre suicidal attempts, disordered body image and social withdrawal. An older sister had been afflicted with Gaucher's disease. About 2½ years prior to this admission, our patient developed hip pain and abdominal discomfort; bone marrow biopsy and splenectomy confirmed the diagnosis of Gaucher's disease. During the next year the patient developed osteomyelitis of the right femur and sustained a pathological fracture of the left hip. Following this he became economically dependent on his wife and the mental symptoms developed.

On admission the patient's liver was enlarged three fingerbreadths; generalized lymphadenopathy and pigmentation of the skin were noted; liver profile indicated some dysfunction; x-rays of the long bones revealed thinning of the cortex and rarefaction of the medullary portions. Both femurs showed evidences of the previous pathology.

The patient was treated with individual psychotherapy and tranquilizers until March 1961 without improvement; instead, he became more delusional and somewhat depressed.

On March 17, 1961 after test doses of 2 and 5 mg. succinylcholine ECT was begun with the following routine: atropine 0.6 mg. was given one half-hour beforehand; at treatment time 6-8 inhalations of a 95% oxygen and 5% CO₂ mixture were administered by BLB mask, followed immediately by 70 mg. succinylcholine chloride I.V. to obtain maximum relaxation. About 15 seconds later (after cir-

cumoral and eyelid fasciculations were noted) the patient was told to hold his breath. After an additional 25 seconds a standard electroshock treatment was given using the unidirectional Reiter machine. Following this an airway was inserted, intermittent pharyngeal suction was used if needed, and the O₂-CO₂ mixture administered using a rebreathing bag which could be rhythmically compressed by hand, if needed. An endotracheal tube was available for emergency use; however, the patient invariably regained spontaneous respiration within 1½-2½ minutes after injection without manual or machine resuscitation. During the series of treatments the patient rarely showed muscular response to ECT, and then only mild twitching of the lower legs. He never complained of anxiety related to ECT or the muscular and respiratory paralysis associated with succinylcholine. Apparently, he did not perceive any discomfort as we continually reassured him he could hold his breath for 25 seconds without difficulty.

After 22 such treatments, the patient showed marked improvement and in June 1961 was given leave from the hospital in an excellent condition.

CONCLUSION

This method can be used with ECT and succinylcholine chloride for maximum muscular relaxation when pentothal or "petit mal technic" to avert anxiety is contraindicated because of liver damage or fragile bony structure as in the present case of Gaucher's disease. The average person can hold his breath for 20-30 seconds without difficulty, especially if he has received several oxygen inhalations beforehand. Thus, he would not be aware of the temporary respiratory paralysis. Correct timing and the patient's confidence are most important in the breath holding routine described. We have tried it in several other less complicated cases with excellent results.

EFFICACY OF ECT FOLLOWING PROLONGED USE OF PSYCHOTROPIC DRUGS¹

KURT WITTON, M.D.²

With the exception of the Rauwolfia derivatives there seems to be no major contraindication to combine or interact the use of electroconvulsive treatment and the tranquilizing and/or antidepressant drugs. During the last two to three years the use of ECT has been stressed again, particularly in cases of failure or resistance to the psychotropic drugs.

I have noted that in many cases refractory to drugs but following a rather prolonged use of phenothiazine derivatives a series of ECT (usually 20 treatments) will obtain a striking unexpected improvement or remission of the active psychotic, mainly schizophrenic, process. This occurs in long term hospitalized as well as in recently admitted patients. It seems to be an interesting fact that the same patients often did not respond to ECT when given prior to the psychotropic drugs. I have observed that particularly delusions of paranoid nature and auditory hallucinations will respond to this "secondary" ECT. I am unaware of the publication of similar observations. From a survey of over 50 cases the following presentations may be significant.

Case 1. A 38-year-old, college educated, divorced male was hospitalized in March 1961 with a severe schizophrenic reaction manifested by auditory hallucinations and delusions of wealth, grandeur and persecution. He had been diagnosed a severe anxiety reaction since 1942 while in military service; he has never shown any psychotic symptoms until admission here. He presented a fixed delusional system centered about his capacity to receive messages from "Novea" (a once existing medieval Catholic temple order), which he believed to be located in the center of the universe, transmitting to him special

signals about world events which enabled him to make business investments and get rich. He thought he earned, thereby, trillions of dollars which he was cheated out of by the F.B.I. and Internal Revenue because he had loaned many trillions to the United States and never got the money back. Intensive drug treatment with high doses of several phenothiazines (thioridazine, trifluoperazine, perphenazine, etc.) combined with imipramine was given over seven months. Numerous intermittent psychotherapeutic interviews with intravenous methylphenidate directed the patient to suppress his delusions and hallucinations but were unsuccessful. While his behavior, mood and affect greatly improved and he had become coherent, relevant and oriented in all spheres he still insisted that he was hearing the voices giving him the messages from "Novea." He finally was placed on EST and following the completion of 20 treatments stated that the messages has ceased and he now felt completely free from the dominance of what he was able to realize, under the drug treatment, to be an imagination. He was continued on a maintenance low dose of phenothiazine and was discharged from the hospital three months later.

Case 2. A 40-year-old single male was admitted in March 1959 with a history of several years of psychotic thinking. He had some hospital treatment before with ECT, described as unsuccessful. He had lived alone, drinking to excess periodically, was described as asocial, seclusive and withdrawn. He was committed after he had threatened to kill all his relatives because he thought they were plotting against him and connived with many communist agents who followed him and threatened his life. He was placed on intensive treatment with high doses of several tranquilizers. He was negativistic, uncooperative and belligerent. After six months of drug therapy he was given a series of 20 ECTs which enabled him to repress the ideas of persecution and reference and made him amenable to psychotherapy, becoming cooperative and friendly and finally making his release possible. He has been out of the hospital for over two years and has adjusted well, not needing any continuation of therapy.

¹ The statements and conclusions published by the author are the result of his own study and do not necessarily reflect the opinion or policy of the Veterans Administration.

HISTORICAL NOTES

HYSTERICAL APHONIA

MURRAY S. WILSON, M.D.¹

Thomas Bowdler (1754-1824) was a physician who devoted a lot of time to removing all allusion to sex from the English language. Not only did he expurgate the plays of Shakespeare, Gibbon's treatise on the Roman Empire, and a section of the Bible, but he also was active in the Proclamation Society that initiated our legacy of censure and censorship of "obscenity." In view of this the hysterical aphonia of his sister Jane (1743-84) is noteworthy.

There were 4 children who survived to maturity, only one of whom ever married, John the oldest. Their background was that of the comfortable English middle-class gentry. When their father married he retired from his London banking business to the life of a country gentleman. He considered the city sinful. His wish for himself was to have been a preacher. Their mother, schooled in French, Latin, philosophy, mathematics, and Hebrew, wrote fanciful religious nonsense, some of which she forced Jane to memorize.

When Jane was 16 she was badly disfigured by smallpox, and at 28 a severe case of measles left her dispirited and unwell. Shortly afterward she was, in the words of her nephew biographer, "much shaken" by attendance at a trial where she gave evidence. She recorded her impressions of the trial in prose and verse.

"A post-boy was apprehended on suspicion of stealing a bank note from a letter, which the author at the request of a friend, had conveyed to the post-office. The circumstances obliged her to appear as an evidence against the unfortunate young man, where she was a witness to the distress of his aged parents, who were waiting at the door of the hall to learn the event of a trial which was to decide the life of an only son. (The offense was capital.) The innocence of his intention appearing very evident, the youth was acquitted."

In the poem the mother tells her husband of a dream.

"Me thought I saw the fatal cord,
I saw him dragged along—

I saw him seized—"She could no more
For anguish stopped her tongue.

But now the voice of joy and woe
To her alike was vain;
Her thoughts still dwelled on Gemmy's fate,
Her lips on Gemmy's name.

Suddenly she stopped—for now in view
The crowded hall appear'd—
Chill horror seiz'd her stiffen'd frame
Her voice no more was heard.

After the trial the mother got her voice back but Jane, again according to her nephew biographer, "was deprived of the power of speech." Thereafter she communicated with her family on the black surface of her slate. In her terminal illness, her sister Harriet noted, "... she grew delirious. Think what we must feel when in that state her voice which had been lost for ten years, returned so that I could distinguish some words and many sentences but almost all wild and incoherent, except once I distinguished my own name, and another time I heard her say 'happy, happy.'"

Her family praised her spirit in her suffering, as, actually, she did herself in the writings posthumously published under the title, *Poems and Essays by a Lady Lately Deceased*. Among the essays are: The Duty and Advantage of Sickness, On Fortitude, On Resignation. In the essay on happiness she wrote,

"Conversation, instead of turning on such subjects as might afford improvement, . . . is often engrossed by the most trifling subjects, so that it is merely an idle dissipation of time . . . Ill nature shelters itself under the mask of wit . . . Vanity flatters the weakness of others in the hope . . . of being flattered in return." Happiness is possible in solitary thought, study, and writing. Throughout the tone is self-righteous and gloomy.

Her recovery of her voice in delirium identifies this as a conversion phenomenon. It was also the compromise of a woman for whom all words had potential danger, not just those of sexual tinge with which her brother, in a fine obsessional compromise, preoccupied himself in his later years.

TORONTO MEETING HIGHLIGHTS

Forty-five hundred members and guests registered for the 118th annual meeting of The American Psychiatric Association at the Royal York Hotel in Toronto, Canada, May 7-11, 1962. Since its founding in 1844, the Association has met in Toronto three times previously, in 1871, 1881 and 1931.

President Walter E. Barton called the meeting to order at 9:00 a.m., Monday, May 7. The Invocation was given by The Reverend A.B.B. Moore, President and Vice-Chancellor of Victoria College, Toronto, followed by Greetings from The Honorable J. Keiller MacKay, Lieutenant-Governor of Ontario; The Honorable M. B. Dymond, Minister of Health for Ontario; and His Worship, Mayor Nathan Phillips of Toronto.

Prize awards were announced as follows: Dr. Karl A. Menninger was given the Isaac Ray Award for his outstanding contributions to improving understanding between the professions of psychiatry and the law. Throughout his professional career, Dr. Menninger, as protagonist for the application of a scientific methodology to the treatment of offenders, has exerted substantial impact on psychiatric and legal thinking. The Award is named in memory of Dr. Isaac Ray, APA Founder and author of a "Treatise on the Medical Jurisprudence of Insanity" (1838), a work which is still quoted with authority.

The Hoffheimer Prize for Research was shared by two research psychologists: Ogden R. Lindsley, Ph.D., Director of Harvard's Behavior Research Laboratory at Metropolitan State Hospital, Waltham, Mass., for his study of chronic psychotic behavior using free operant conditioning methods; and to Joseph D. Matarazzo, Chairman of the Dept. of Medical Psychology at the University of Oregon School of Medicine, for his study on the influence of the interviewer on the speech behavior of interviewees. Both recipients are under 40 as required by the terms of the Award which was established in 1947 in memory of Lester N. Hoffheimer of New York City

who lost his life in action in World War II. This is the first time the award has been divided between two persons working independently.

The George N. Raines Award for a doctoral thesis on a biological subject related to mental disorders was given to Marcus M. Jensen, Ph.D., University of California, Los Angeles, for his work on "Sound Stress and Susceptibility to Vesicular Stomatitis Viries."

The 1961 Mental Hospital Achievement Awards were announced as follows: Greater Kansas City Mental Health Foundation (Gold Award); Illinois State Psychiatric Institute (Silver Award); and Psychiatric Research Institute, London, Ontario (Bronze Award).

The opening session also heard the Report of the Medical Director who emphasized the function of his office as the administrative arm for the Officers, Councilors, Committees, District Branches, and as a service agency for the members at large.

The Speaker of the Assembly of District Branches, Dr. Edward G. Billings, reported that there were now 56 Branches with a membership totalling over 7000. He noted that 28 Branches are already processing applications for membership in the Association, and that 30 of them publish their own newsletters. Dr. Billings made it clear that in less than a decade the District Branch movement had matured to the point that the Branches were exercising active leadership in behalf of better mental health for the nation, a leadership which would inevitably grow stronger from year to year. He especially stressed the great contribution that the Branches could make to the orientation of state and local medical societies in the needs and problems of our field.

Dr. Aldwyn B. Stokes, Chairman, reported for the Committee on Arrangements. It must be noted that the annual meeting arrangements this year, including the Ladies Program planned by Mrs. K. G. Gray and her special committee, were not

only exceptionally well organized, but characterized by a quality of cordiality and hospitality on the part of Toronto colleagues and their families that made this meeting as enjoyable as any in the Association's history. Literally hundreds of U. S. members were entertained in the homes of Toronto psychiatrists. All who attended will express their profound appreciation.

A new precedent was established this year by way of memorializing deceased members. Their names were inscribed by an artist on a parchment scroll which was placed in the main meeting room throughout the week on a handsome lectern constructed with great skill and care by craftsmen at the Ontario Hospital, Penetanguishene, Canada. The scroll will be filed in a bound volume from year to year and deposited permanently in APA's Historical Library at the Central Office in Washington.

The Chairman of the Program Committee, Dr. John Donnelly, in his report noted that of 406 papers submitted for presentation this year, only 110 could appear on the program, in accordance with the policy of the committee that the number of presentations should be sufficiently limited to allow adequate time for delivery and discussion.

The Secretary and the Treasurer also gave their official reports at the opening session, summaries of which will be published in another issue of the Journal.

It was announced that District Branches had approved 196 applications for membership in the Association, and the election of 487 others was approved at this meeting, as were 219 new Fellows, 265 transfers from Associate to Full Membership, and three Corresponding Fellows. This brings APA membership to approximately 13,000. Judge David L. Bazelon, Ralph C. Busser, and Sir Aubrey Lewis were made Honorary Fellows.

The above reports were followed by a distinguished Presidential Address by Dr. Barton, published in full in this Journal. The Address made these salient points, among others: 1. *Action for Mental Health*, the Final Report of the Joint Commission on Mental Illness and Health, offers psychiatry the greatest opportunity it will have in this decade to advance training, treat-

ment and research. 2. The Association should more readily express itself on social issues of great relevance to the future of medicine and psychiatry. 3. Canadian members should, if they wish, make clear their primary allegiance to the Canadian Psychiatric Association. This would in no wise jeopardize useful liaison relationships between the APA and other independent national psychiatric organizations, not only in Canada, but in other countries. 4. Psychiatry must continue to move closer to the main stream of medicine. Second-class medicine in public mental hospitals can no longer be condoned for any cause. 5. In the coming decade the problems of the aging will compel our special attention.

The opening session closed with a Response to the Presidential Address by the President-Elect, Dr. C. H. Hardin Branch and a Benediction by The Reverend L. K. Shook, Professor of English at St. Michael's College in Toronto.

A second business session was held on Tuesday afternoon, May 8, at which the Chairman of the Board of Tellers announced the election of new officers as follows: President-Elect, Dr. Jack R. Ewalt; Vice-Presidents, Drs. Alfred Paul Bay and John R. Saunders; Secretary, Dr. Harvey J. Tompkins; Treasurer, Dr. Addison M. Duval; and Councilors (for three-year terms), Drs. John Donnelly, Othilda Krug, and Lauren H. Smith. The retiring President, Dr. Walter E. Barton, will also serve for three years on the Council. Dr. Lee Sewall, Chairman of the Committee on Constitution and By-Laws, presented the Proposed Amendments to the Constitution and By-Laws of the Association, copies of which had been distributed to the membership and which will be voted on by mail ballot in the coming year. The Secretary gave his report of Actions of Council over the preceding year for approval by the membership.

The Convocation for the newly elected Fellows was held on Tuesday, May 8, in Convocation Hall at the University of Toronto. One of the great organizers of the British Commonwealth, Dr. Healey Willan, provided the music for the occasion. Dr. H. Northrop Frye, Principal of Victoria College at the University and one of

Canada's leading literary critics, delivered the Fellowship Lecture on "The Imaginative and the Imaginary"—a charming discourse in which he elaborated on the nature of imaginative creativity in literature and distinguished it from the "imaginary" of the disordered mind. Following the formal Convocation, a reception for the new Fellows was held in the Great Hall of Hart House on the University campus. Never before had the Convocation been held in such an appropriate academic setting and the hope was widely expressed that the precedent might be followed from year to year.

A third business session was held on Wednesday morning, May 9, at which time reports of the three Coordinating Committee Chairmen, Drs. Dana L. Farnsworth, Howard P. Rome, and Paul V. Lemkau, were received. These reports highlighted major committee concerns and activities over the past year revealing once again the fundamental role of the Committees in inaugurating, supporting, and guiding the Association's major programs and services.

The annual Wednesday evening banquet was a most festive occasion devoid of formalities except for the presentation of the Past President's Badge to Dr. Barton by Dr. Winfred Overholser followed by the presentation of a handsome editorial chair to Dr. Clarence B. Farrar as a symbol of regard and appreciation for his dedicated editorship of *The American Journal of Psychiatry* since 1931. Quite as moving was Dr. Farrar's response to the tribute. The dinner was followed by dancing until 2:00 a.m.

The final business session on Friday

morning witnessed the introduction of the incoming President, Dr. C. H. Hardin Branch, the presentation of certificates to retiring officers, and the Secretary's report of actions of Council which had met the day before. Dr. Robert S. Garber was announced as the new Speaker-Elect and Dr. Hamilton Ford as the new Recorder of the District Branch Assembly.

Other features of the Toronto meeting worthy of special mention were these: A "Question the Expert" session was introduced for the first time in which program outstanding psychiatric leaders and scholars volunteered to subject themselves to random questions from an eager audience on such subjects as perspectives in psychiatry, heredity versus environment, basic issues in research, epidemiology, the future of mental hospitals, and others. Unquestionably, the innovation was very well received. Special mention should also be made of the splendid Adolf Meyer Research Lecture given by Dr. Tigani el Mahi of Alexandria, Egypt, on "The Evolutionary Concept of Mental Health, Its Entity and Identity."

It was generally agreed that press coverage of the meeting was exceptionally good with approximately 50 science writers and reporters in attendance.

For these reasons it was with a special enthusiasm that the 118th annual meeting went on record in praise and commendation for the work of the Arrangements Committee under the Co-Chairmen, Drs. Stokes, Griffin, and McNeel, and the Program Committee chaired by Dr. Donnelly.

Harvey J. Tompkins, M.D.,
Secretary.

WANT-NEED

Faites du bien aux pauvres . . . Oui, mais aux vrai pauvres, aux pauvres d'esprit, et non pas en leur octroyant la faveur qu'ils vous demandent, mais celle dont ils ont besoin.

—MIGUEL DE UNAMUNO

CORRESPONDENCE

COMMUNICATION AMONGST AUTOMATA

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : He who negates the existence of "negation" clearly puts himself into a paradoxical situation, and even printers of a journal of psychiatry shouldn't get away with this. In my recent article, "Communication amongst Automata" (118 : 865, 1962), they denied me the privilege to negate a proposition "x" which is usually denoted by placing a horizontal bar "-" over the proposition "x", indicating "non-x" or "it is untrue that x is the case." Hence, all the logical equations in the left column of page 867 must appear as puzzling chicken-tracks unless they are corrected to read :

$$\begin{aligned} & x \ \& \ (y \vee \bar{y}) \\ & y \ \& \ (x \vee \bar{x}) \end{aligned}$$

including the corrected truth-table :

x	y	P	B
		$x \ \& \ (y \vee \bar{y})$	$y \ \& \ (x \vee \bar{x})$
0	0	0	0
0	1	0	1
1	0	1	0
1	1	1	1

However, it is heartening to see that we still live in a world where errors are made and where they can be corrected and forgiven. We will be denied these pleasures when the Automaton takes over.

Heinz Von Foerster,
University of Illinois,
Urbana, Illinois.

PHENMETRAZINE HCL ADDICTION

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : In my article "Addiction to Phenmetrazine HCl" in Am. J. Psychiatry, 118 : 6, it has been pointed out by Prof. M. Bleuler of the Zürich Psychiatrische Universitätsklinik, Dr. I. Pierce James of the Royal Perth Hospital, Australia, and Dr. Francis X. Trimble of Long Beach Hospital, California, that I omitted European references on addiction to this drug. Dr. J. A. Rosen of Philadelphia points out that the first American article on this subject was pub-

lished by him in the *Journal of the American Osteopathic Association* in 1959. My article should have stated that there were no previous articles on the subject in American medical publications and I wish so to amend it. The doctors have stressed the possibility of addiction and point out that my case is not a single isolated rarity as it would appear from my article.

Kannan Building,
Lawrence, Mass.

RE : COMPAZINE SUPPOSITORIES

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : In reference to the communication by Dr. James K. McDonald in your February issue concerning an attempted suicide with Compazine suppositories you might be interested in the following report.

A young woman was referred to my office by an ear-nose-throat specialist. She developed in the last 48 hours violent spasms of tonic-clonic type in form of an opisthotonus accompanied by protrusion of tongue and sensation of choking. The history revealed that she had turned to her family

physician for advice: being a religious Jewess she intended to fast on Atonement Day (Yom Kippur). However she used to have difficulties with fasting before because she developed nausea and even vomiting when fasting. The physician had the idea to prescribe 2 Compazine suppositories in 24 hours since religion did not permit her to swallow any medicines except in greatest emergency.

She was in a state of panic and mere reassurance was sufficient. She lost her symptom, as I heard, the next day. The fact that she was fasting might have increased the effect of the drug. In rectally applied drugs it is very difficult to state as the

manufacturer indicates that 25 mgm. corresponds to 15 mgm. orally since rectal absorption in man shows notoriously great variations.

The described spasms represent a form of "akathisia" an extra-pyramidal symptom well known as a side effect of phenothiazines.

If compazine is, according to the manufacturer, counter-indicated in states of depression of central nervous system activity it might be also counter-indicated in starvation.

Joseph Wilder, M.D.,

New York 28, N. Y.

• RE: EXPERIENCES WITH ELAVIL

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: The interchange in "Correspondence" (Feb. 1962) in regard to the sleepiness produced by Elavil is of interest. It is rare indeed that a reader can find an opportunity to correlate both points of view.

Sleepiness is a "side effect" with Elavil in patients who are depressed and retarded, without agitation. Neurotic depressions frequently show this side effect. However, in the involutional psychotic this is most re-

warding. Here it is therapeutic and is not a "side effect." (Dorfman, W.: *Psychosomatics*, May-June 1960). As for its value in insomnia, recent experiences have indicated that where Tofranil is preferred in the daytime because of the sleepiness effect of Elavil, the addition of 50 mg. of Elavil at night will help break addiction to barbiturates. Unfortunately, Elavil cannot be combined with MAO drugs.

Wilfred Dorfman, M.D.,
Brooklyn, N. Y.

ACTION FOR MENTAL HEALTH

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: The January *Newsletter* says that Council has been developing a "position statement" on the Final Report of the Joint Commission on Mental Illness and Health. May I add one, lone, small voice to help the Council in its deliberations?

First of all, as a practitioner of general psychiatry, I agree with much of the report, particularly that portion which says that we must approach the public realistically with the recognition that mental illnesses are "different" from other illnesses. I, too, have a deep appreciation of the historic significance of *Action For Mental Health*. One statement of the report, how-

ever, which appeared very early in the Commission's summary of the status of psychiatric treatment today, should not, in my opinion, go unchallenged.

This statement says, in effect, that many years ago fear was used in the treatment of the mentally ill and that the efficacy of electroshock treatment, as used today, is probably due to the fact that it induces fear in the patient.

This statement has a first cousin, or brother, which does something like this: "Shocktreatment works because the patient feels it is punishment and, in undergoing it, he expiates his guilt—or shocktreatment works because it is a symbolic death to the patient." Propositions like this, of course,

are facile, doctrinaire, off-the-top-of-the-head statements which are neither scientifically provable or disprovable. The statement that shocktreatment works because of the fear it induces fortunately is disprovable. Anyone who has administered ECT, using sodium pentothal or some other anesthetic for the treatment, and who has had as a result patients returning as outpatients to his office or clinic, time after time for treatment, knows from experience and his patients' cooperation that the element of fear has been abolished. To him, the statement about shocktreatment in *Action for Mental Health* is disproved.

As has been intimated, the majority of the report I can subscribe to wholeheartedly. The statement about shocktreatment,

however, is disquieting. Now that President Kennedy has announced that he is giving this report to Secretary Ribicoff and other members of the Federal Government to study, it seems to me important that a statement of a committee of eminent psychiatrists should not contain biased opinions. As one who has used ECT many, many times with the practical result of getting the patient back to efficient operation, I would like to register my protest that any official opinion by representatives of American psychiatry should dispense with such a useful therapeutic measure on purely doctrinaire grounds.

R. J. Dickinson, M.D.,
220 Center Street,
Ridgway, Pa.

DIAGNOSTIC EVALUATION AND TREATMENT SHOULD BE WITHIN THE CONTEXT OF LIFE

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: A woman patient who was deeply upset by her husband's unfaithfulness came to see me, accompanied by her father. The husband did not deny having affairs but claimed that "he could not allow her jealousy to interfere with his leading a normal life." She had already seen several psychiatrists, some of whom wanted to institutionalise her. I thought her reaction not irrational, but tried to conciliate. When her father told me however, "Madame, I am a Parisian and know life, but when my son-in-law, after behaving as he did, quotes Freud and wants to lock up my daughter, this is too much." I was lost for a reply. I learned two years later that the patient had seen altogether twenty psychiatrists, eighteen of whom considered her "paranoid" with only myself and a Swiss psychiatrist dissenting. The latter said to her: "What you need is a lawyer, not a doctor." Today she is divorced.

When I interviewed an apathetic patient in a Federal Hospital, I succeeded in evoking a strong response by discussing the fact that she had a 10-year prison sentence hanging over her head. The Chief wrote me afterwards that "since this demonstra-

tion some of the residents believe now that reality factors should be discussed." I replied that I had not known that anybody ever thought otherwise, but learned since that unfortunately the distinction between endogenous and exogenous is often neglected.

A young girl who had treatment since the age of 12 came to see me in an acute anxiety condition. Her doctor had all along encouraged her to leave home at the age of 18, but when she did so in order to live with a homosexual friend, it proved a failure. Her therapist then broke off treatment saying that she must learn "to cope with her anxiety." I dwelt little on her emotions but high-lighted the fact that she was unable to earn her living, and that this caused, to quite a degree, her anxiety. After a few weeks she resentfully stopped treatment, but took a job which she has held ever since.

Not all painful emotions are abnormal and it is essential to assess and rectify their cause. After 3 years "supportive treatment" a social agency referred to me a girl of 15 who looked more like a prostitute of 50. She complained of her "sense of inferiority" and that she imagined people stared at her. I told her that this was actually the case,

and explained why she attracted attention and told her how she ought to dress. She took my criticism well and acted on it, and as a result looked better and felt better.

A boy of 19 who was referred to me as a "wild-eyed, deluded schizophrenic" believed he was the "greatest genius who ever lived." He had had several years of treatment and his last psychiatrist used to reassure him: "Do not doubt yourself," thus only strengthening his ideas of grandeur.

In contrast, I told him his quotations from Dostoevsky were wrong and pointed to other flaws in his knowledge. This brought him down to earth somewhat and enabled me to establish a relationship. Today he has completed his studies very successfully and is happily married.

MELLARIL : EJACULATION DISORDERS

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR: Several correspondents to the *Journal* have recently reported their experiences with patients who have demonstrated disorder of ejaculation during the course of therapy with Mellaril. Perhaps this case report could be added to those which now seem to be rapidly accumulating.

The case in question is that of a 47-year-old married, white male, who was recently hospitalized for three weeks with an acute manic psychosis. In addition to four electroconvulsive treatments, he received 100 mg. of Mellaril q.i.d. He entered a rapid and adequate remission, returned home and resumed his occupation as well as his customary marital relations. At this point, he reported the typical Mellaril affect, namely,

an ability to achieve a full and complete erection without subsequent orgasm or ejaculation.

In view of the paucity of knowledge of the physiologic function of the male sexual apparatus, it would seem that this specific and peculiar affect of Mellaril deserves some investigative attention. One would wonder whether our colleagues in urology might not have further observations. One also wonders whether this is not a far more wide spread occurrence from this drug with its failure to be reported reflecting the characteristic reluctance of the male to discuss any alterations in his sexual potency.

Fort Lauderdale, Fla.

SPECIAL REPORTS

EXPANDING GOALS OF GENETICS IN PSYCHIATRY (1936-1961)

On October 27-28, 1961, a special symposium was held at the New York State Psychiatric Institute, marking the 25th anniversary of the Department of Medical Genetics. Under the auspices of the New York State Department of Mental Hygiene and the Department of Psychiatry, College of Physicians and Surgeons, Columbia University, the symposium also served as the sixth annual meeting of the Eastern Psychiatric Research Association. It was cosponsored by the Academy of Psychosomatic Medicine, the American Eugenics Society, the American Psychopathological Association, the American Society of Human Genetics and the Scottish Rite Committee on Research in Schizophrenia. The program chairman was Dr. Franz J. Kallmann, Chief of Psychiatric Research (Medical Genetics), New York State Psychiatric Institute and Professor of Psychiatry, Columbia University. The Sponsoring Committee consisted of 35 eminent persons in the fields of psychiatry, medical education, vocational rehabilitation, genetics and biology. The meetings were attended by over 250 guests from all parts of the country and abroad, and included 22 invited papers and discussion. An overflow audience saw and heard the proceedings by closed circuit television.

The opening session "Progress in Behavioral and Psychiatric Genetics" was called to order by Dr. Paul H. Hoch, Chairman. Vice-chairman was Dr. Lauretta Bender. Dr. John D. Rainer spoke on "Studies in the Genetics of Disordered Behavior, Methods and Objectives," emphasizing the various fields of interest involved in the study of human behavior in its genetic and biologic framework. Other speakers were: Dr. Lissy F. Jarvik: "Genetic Variations in Disease Resistance and Survival Potential," a twin research on tuberculosis and on senescence; Dr. Jerry Hirsch: "The Contribution of Behavior Genetics to the Study of Behavior." Finally, reports on two cur-

rent research projects at the Psychiatric Institute were presented, one on "Changing Mating and Fertility Patterns in Schizophrenia" by Drs. Loise Erlenmeyer-Kimling and Charles Goldfarb, the other on "Deafness and Schizophrenia" by Drs. Kenneth Z. Altshuler and M. Bruce Sarlin. The former represented a preliminary report on a study of a random sample of schizophrenic patients admitted in the years 1934-36 and 1954-56, indicating an increase in the overall fertility rate of schizophrenic patients during this 20-year period. The paper of Altshuler and Sarlin reported findings from a large scale psychiatric project for the deaf.

On the afternoon of the first day, "Progress in Basic Genetics" was presented by a distinguished panel of scientists under the chairmanship of Dr. H. Bentley Glass, Professor of Biology, Johns Hopkins University. Prof. M. J. Kopac (New York University), gave an illustrated talk on "Structure and Micromanipulation of Chromosomes." Dr. Malcolm A. Ferguson-Smith (University of Glasgow) presented an authoritative report on modern discoveries in cytogenetics as related to sexual development. Among the syndromes discussed were Klinefelter's Syndrome, Turner's Syndrome and various trisomy conditions. On the biochemical level, Dr. Carl C. Lindegren, Director, Biological Research Laboratory, Southern Illinois University, presented an unorthodox but thought-provoking discussion of the "Biological Function of Deoxyribonucleic Acid," with emphasis on cytoplasmic induction of gene function. Prof. K. C. Atwood (University of Illinois) reviewed with great clarity some very recent crucial experiments, illuminating the nature of the information-bearing and replicating functions of the genetic material. Finally, Dr. W. Eugene Knox, Visiting Professor of Biochemistry, American University, Beirut, Lebanon, spoke on "Biochemical Genetics and Human Metabolism," illustrating the

interaction between environment and gene action in the molecular-enzymatic sphere, and discussed sickle cell anemia, galactosemia and phenylketonuria.

The principal speaker at the Banquet Session on the evening of October 27, chaired by Dr. Lawrence C. Kolb, was Dr. J. A. Fraser Roberts, Director, Clinical Genetics Research Unit (Medical Research Council), London, whose topic was "Genetics in the Medical School Curriculum." His advice was to teach genetics to beginning medical students by means of didactic lectures, follow this by illustrative material in the clinical years and in particular allow psychiatric genetics to be taught by psychiatrists, versed in the particular terminological and diagnostic standards of their specialty. Other speakers at this evening session included Dr. Hoch, Dr. Merritt, Dean of the College of Physicians and Surgeons, Dr. William Malamud, representing the American Psychiatric Association, Dr. Edward Tatum, Nobel-laureate of the Rockefeller Institute, Dr. Glass and Dr. Sandor Rado, Dean of the New York School of Psychiatry.

Dr. Impastato, secretary-treasurer of the Eastern Psychiatric Research Association, presented Dr. Kallmann with the handsome gold medal awarded by the Association for extraordinary contribution to psychiatry.

Saturday morning's session, under the chairmanship of Dr. Charles Buckman, and Dr. Impastato, dealt with "Progress in Clinical Genetics." Drs. Arthur Falek and Edward V. Glanville spoke on "Investigation of Genetic Carriers," concentrating on psychiatric and neurological conditions, including Huntington's chorea. Preliminary data on the use of an electronic tremor recording device in the early detection of this disease were presented. Dr. W. Edwards Deming spoke on "Methods of Sampling Design in Psychiatric Genetic Studies," and Dr. Walter F. Haberlandt of the Psychiatric University Clinic, Düsseldorf, reviewed

"Progress in Neurological Genetics." Dr. George A. Jervis (Letchworth Village) discussed genetic aspects of undifferentiated retardation, and phenylketonuria. Dr. Gordon Allen (National Institute of Mental Health) presented "Twin Data on Mental Deficiency." Diane Sank and Dr. Jane Weiss discussed "Genetic and Adjustive Aspects of Total Deafness," referring to the psychological and genetic data obtained from general population and twin surveys.

The final session on October 28 (Chairman, Dr. Malamud) dealt with "Functions of a Medical Genetics Department in the Mental Health Field."

Dr. Eliot Slater, Director, Medical Research Council, Psychiatric Genetics Unit, London, reported on "Trends in Psychiatric Genetics in England," with reference to both cytological and clinical studies; Dr. Erik Strömberg, Professor of Psychiatry, Aarhus University, spoke on current research in Denmark and other Scandinavian countries; Dr. Lewis Hurst, Professor of Psychological Medicine, University of the Witwatersrand, Johannesburg, described the organization of genetic research in South Africa. Dr. C. Nash Herndon (The Bowman Gray School of Medicine, Winston-Salem), spoke on "Medical Genetics in the United States." He emphasized the pioneer role of Dr. Franz Kallmann in this field. Dr. Kallmann, the final speaker, discussed "Genetic Research and Counseling in the Mental Health Field." The keynote of Dr. Kallmann's address was the importance of making available well-informed, non-traumatic genetic counseling.

The meeting ended with the presentation of the R. Thornton Wilson Awards in Genetic and Preventive Psychiatry. The prize for the best paper in the clinical area went to Drs. Altshuler and Sarlin; in the basic sciences to Dr. Ferguson-Smith. Dr. Malamud closed this most successful meeting at 6:00 p.m. on October 28.

JOHN D. RAINER, M.D.

REPORT ON THE 10th ANNUAL CONFERENCE OF THE AMERICAN SOCIETY OF ADLERIAN PSYCHOLOGY

After his break with Freud, in 1911, Alfred Adler developed his own school of *Individual Psychology*. The American Society of Adlerian Psychology, therefore, celebrated 50 years of Adlerian Psychology at its 10th annual meeting, in New York City, November 3-5, 1961.

The papers given clustered around the following topics: the historical development of Individual Psychology, presented by Alexandra Adler (N. Y.), A. Farau (N. Y.), and a delightful series of vignettes of Adler's warm, perceptive, and energetic personality given by his co-workers and friends in recollections of their personal experiences.

The impact of the actual political situation on all our thinking showed in papers on "The Meaning of Panic" (R. Dreikurs, Chicago), and on "The Atomic Threat—A Challenge to Individual Psychology" (L. Sicher, Los Angeles). These presentations were followed by an earnest discussion on what psychotherapists could contribute to the prevention of war.

The next topic centered around child therapy and guidance, introduced by an original short sound film, showing Alfred Adler talking on "Problem Children." E. Papanek (N. Y.) spoke on "Adlerian Concepts in Child Development"; D. Deutsch (N. Y.) led a panel discussion on "Child Guidance: Retrospect and Prospect"; M. Sonstegard (Cedar Falls, Iowa) and E. Thoma (N. Y.) dealt with the problem of "Underachieving School Children."

Papers dealing with psychotherapeutic theory and practice were presented by the president of the Society, B. Shulman (Chicago), on "The Difference Between the Schizophrenic and Manic-depressive Psychoses," by G. Fenchel (N. Y.) on "The

Concept of Purpose in Psychotherapy," by A. Kadis (N. Y.) and N. Freedman (N. Y.) on "Changes in Early Childhood Recollections During Therapy," by H. Papanek (N. Y.) on "Overt Expression of Hostile Feelings in the Therapy Group," and by I. Neufeld (N. Y.) on "Phenomenological Approach to Psychosomatic Processes."

The field of mental hygiene and social psychology was represented by H. Ansbacher (Burlington, Vt.) dealing with "Mental Hygiene Value of an Academic Course in Individual Psychology," by J. Meiers (N. Y.) on "The Mental Hygiene System in the U. S. A.," by L. Rattner (N. Y.) speaking on "The Concept of Power in Individual Psychology," and by N. Ionedes (Wash., D. C.) on "Adlerian Principles in the Treatment of Offenders."

J. B. Rotter (Columbus, Ohio) was guest speaker at the dinner. His talk on "Analysis of Adlerian Psychology from the Viewpoint of Research" was extremely stimulating and provoked an interesting discussion on the verifiability of any personality theory with special emphasis on the possibility of research concerning Adlerian basic assumptions, e.g., the importance of inferiority feeling, of compensation and over-compensation, and of social feeling in the development of the child.

The conference ended with a panel discussion on "Outlook and Challenge," in which, under the chairmanship of Alexandra Adler (N. Y.), the new generation of Individual Psychologists discussed plans for the future of their fields of interest: training and research, theory of personality, techniques of psychotherapy, and the growing importance of social psychiatry.

Helene Papanek, M.D.

NEWS AND NOTES

NIH RESEARCH CAREER AWARD PROGRAM.—\$291,796 in grants have been awarded to sixteen persons by the NIMH, Bethesda, Md., under the new NIH Research Award Program. This program is to strengthen research on the problems of mental health and mental illness by providing career support to highly qualified persons. Two types of awards are available, the Research Career Development Awards and the Research Career Awards.*

THE PHILOSOPHY OF PSYCHIATRY.—The University of Cincinnati has announced the establishment of a course of doctoral study "in the philosophical implications and moral presuppositions of psychiatry." This study will involve a "direct experimental approach to problems common to psychiatry and philosophy."

The new program is the outgrowth of many years of close cooperation between philosophy and psychiatry at the University of Cincinnati carried on under the direction of Dr. Campbell Crockett, Dean of the Graduate School, and Dr. Maurice Levine, Head of the College's Dept. of Psychiatry.

DR. MYERS TO SUCCEED DR. LAUREN H. SMITH AT PENNSYLVANIA HOSPITAL.—On retirement of Dr. Lauren Smith, the present physician-in-chief of the Institute of Pennsylvania Hospital, July 1, 1962 to become full time consultant for development to the Institute, J. Marvin Myers, Jr., M.D., will become medical director of the Institute.

Dr. Myers is a graduate in medicine from the Johns Hopkins School of Medicine (1943) and has had five years' residency training at the Henry Phipps Psychiatric Clinic, Johns Hopkins Hospital. He has been on the Pennsylvania Hospital staff since 1951.

ILLINOIS PSYCHIATRIC SOCIETY.—On May 16, 1962 the following members were elected to office for the year 1962-63: President, Dr. Lester H. Rudy; President-Elect,

Dr. Arthur A. Miller; Secretary-Treasurer, Dr. Donald Oken; Delegates to American Psychiatric Association Assembly, Dr. John Adams, Dr. Jewett Goldsmith (Alternate); Councilors, Dr. Melvin Sabshin, Dr. Harold M. Visotsky, Dr. Thomas T. Turlentes, Dr. Rudolph G. Novick.

DR. RICHARD CAMERON TO HEAD THE NEWBERRY (MICHIGAN) STATE HOSPITAL.—Dr. Richard R. Cameron has been appointed Medical Superintendent of Newberry State Hospital to succeed Dr. T. W. Thompson on the retirement of the latter. The appointment is effective June 16, 1962.

Dr. Cameron is a graduate of the Jefferson Medical College of Philadelphia and is Board-certified in both psychiatry and neurology. From 1938 to 1958 he was in the military service, occupying various medical, psychiatric and administrative posts. He has been attached to the central office of the Michigan Dept. of Mental Health where he has had mainly to do with hospitalization problems.

SECOND INTERNATIONAL CONFERENCE ON "BIOLOGICAL TREATMENT OF MENTAL ILLNESS."—Attention is again called to this important International Conference to be held Oct. 31 to Nov. 3, 1962, at the New York Academy of Medicine. Sub-topics of the Conference are: 1. Theory and Physiology; 2. Specific Plasma Protein Factors in Relation to Schizophrenia; 3. Mental Health Conditions and Psychiatric Treatment in Ceylon, Thailand, Formosa, and Africa; 4. Psychopharmacology; 5. Endocrinology; 6. Various Shock Treatments. Scientists from every continent will participate.

Dr. D. Ewen Cameron, Chairman of the Dept. of Psychiatry of McGill University, will be the Honorary President.

Physicians, psychiatrists, psychologists, social workers, and anyone interested in the field of mental health are invited. For more detailed information, write to the Chairmen of the Conference: 1. Max Rinkel, M.D., Massachusetts Mental Health Center, 74

Fenwood Road, Boston 15, Mass. (Office Address : 479 Commonwealth Avenue, Boston 15, Mass.) ; 2. Harold E. Himwich, M.D., Galesburg State Research Hospital, Galesburg, Ill.

THE PRESIDENT'S COMMITTEE ON JUVENILE DELINQUENCY AND CRIME.—On May 31, 1962, the President, on the basis of a report of the year's activities of the President's Committee on Juvenile Delinquency and Youth Crime, announced a Federal grant to Mobilization For Youth, Inc., on the Lower East Side of New York City, the first demonstration *action* grant made under the Juvenile Delinquency and Youth Offenses Control Act of 1961.

Six other cities have received grants under the Act for planning demonstration projects : New Haven, Houston, Cleveland, Philadelphia, Los Angeles and Minneapolis. Each city has set up an organization to develop a comprehensive program involving public and private agencies dealing with youth. These broad new attacks on delinquency will give a great opportunity to qualified personnel to aid in establishing community-wide youth development programs.

Many other cities throughout the country have shown an interest in establishing an overall youth development program ; they also need the help of experienced personnel.

The Committee has also announced a training grant for a two-week summer work conference on the education of disturbed and delinquent children. The conference will be held at the Hawthorne Cedar Knolls School, in Hawthorne, N. Y., from July 9 through July 20, 1962.

This Work Conference is co-sponsored by Union Free School District #3 (Mt. Pleasant, New York) and Columbia University. Registrants are eligible to receive two

points of graduate credit for participation in the two-week training program. Twenty-five educators will be enrolled.

Applications must be filed by June 15. For further information, write : Dept. of Special Education, Teachers College, Columbia University, New York 27, N.Y.

NEW YORK STATE PSYCHIATRIC INSTITUTE.—Professor Howard Hunt joined the staff of the N. Y. State Psychiatric Institute on July 1, 1962 as Chief of Psychiatric Research (Psychology). In addition to this position he will be appointed Professor of Psychology at Columbia University. Professor Hunt has resigned as Professor and Chairman of the Department of Psychology at the University of Chicago.

MENTAL ILLNESS: A GUIDE FOR THE FAMILY.—A new fourth edition of this 95-page book by Edith M. Stern has recently been issued by the National Association for Mental Health. First published in 1942, more than 300,000 copies of the Guide have been distributed. The purpose of the book is "to combat common fallacies about mental illness" and is "addressed specifically, personally and directly to the troubled, unhappy relatives of the mentally ill."

Copies (price 50¢) may be obtained from the National Association for Mental Health, 10 Columbus Circle, New York 19, N. Y.

CORRECTION.—Soll Goodman, M.D., secretary to the Board of the American Orthopsychiatric Association calls our attention to the fact that an error appeared in our columns of March 1962. Edward D. Greenwood, M.D., now President of the Association, should have been listed as President-Elect rather than George E. Gardner, M.D.

BOOK REVIEWS

NARRATIVE OF A CHILD ANALYSIS. By Melanie Klein. (New York: Basic Books, 1961, pp. 496. \$10.00.)

In *Narrative of a Child Analysis* Melanie Klein presents her theories in their final, authoritative form. She describes in detail 93 psychoanalytic sessions with a ten-year-old boy extending over about 4 months. Her comments about theory and technique are placed at the end of each session. There are 73 illustrations of the boy's pencil and crayon drawings, some in color. Unfortunately Melanie Klein did not live to see the publication of this, her most comprehensive work.

This book is well written and of great historic importance for child psychiatry. It is unique because here we have for the first time a detailed day-to-day description of a complete, even though not completed, psychoanalysis of a child.

Mrs. Klein states that she selected the case of Richard as an example to demonstrate her technique because "the unusual cooperativeness of the child enabled me to penetrate to great depth," in spite of the fact that the analysis had to be limited to 4 months from the beginning. Richard suffered from what we would call "school phobia." He had been too fearful to attend school since the outbreak of the war in 1939 when he was 8 years old. It is characteristic for Melanie Klein's theoretical and practical approach that she finds the fact that the onset of this very severe symptom coincided with the outbreak of the war of no importance. She states that the war only "increased his anxieties." Actually the appearance of such a severe symptom is never only a change in quantity but one in quality. Richard was afraid of other children, avoided going out by himself, suffered from hypochondriasis and depressions.

The analysis was carried out in a village in England in the spring and summer of 1941 at the time of the Blitz and when Hitler attacked the Soviet Union. Richard "followed the news closely and took great interest in the changes in the war situation." Melanie Klein refers to the "frightening external circumstances" under which both she and the child had to live. The analysis, however, concerns itself entirely with "anxiety concerning internal processes" because "fears of external dangers are intensified by anxieties arising in the earliest stages" (of infantile development)

and "therefore the anxiety aroused by actual dangers can be diminished by analysis." In this way Melanie Klein re-emphasizes the basic position she shares with many other psychoanalysts, namely "that the unconscious is at the root of all mental processes, determines the whole of mental life." (The Psychoanalytic Study of the Child, Vol. VII, 1952.) This means giving the unconscious priority and power over all other aspects of man's life. It means separating it from physical, intellectual, social and economic forces as though it were a self-contained unit, when actually all these forces influence each other crucially in what Wertham calls "dynamic interaction."

Melanie Klein had her own psychoanalytic school in England. She differed considerably from Anna Freud, Edward Glover and Ernest Jones, all of whom practiced in London during the same period. She was a pupil of Karl Abraham in Berlin and was much influenced by his theories of oral, anal and genital stages of the libido. Freud did not accept all her theories which, even though they concur with most of his basic ideas, go much further in the role they ascribe to the unconscious, and especially in their stress of early infancy, before speech has developed, as the crucial time of life, because this is when the earliest stages of the Oedipus complex are supposed to take place. It sometimes seems as though Klein had carried psychoanalysis *ad absurdum*.

Klein's psychoanalytic procedure consists "in selecting the most urgent aspects of the material and interpreting them with precision." Interpretations dominate the sessions from the first one on. This is true even when one allows for abbreviations of descriptions of the sessions which are necessary in writing such a book. One does not get the impression that the patient ever has a chance really to tell his story or his side of the story. He is immediately overwhelmed with forceful interpretations. Many of them must have been experienced by him as accusations, and all of them were strong suggestions against which a child is defenseless, especially such a young child suffering from hypochondriasis.

No diagnosis is made. Melanie Klein does not seem to distinguish between neurosis and schizophrenia in any case, for "psychotic" and "persecutory" anxiety is supposed to be present in all cases. In the 27th session Richard expresses the fear of being poisoned; only then did he feel free to mention this. Emphasis on

examination instead of interpretations should have revealed such an important symptom in the beginning. Even then the symptom is not analyzed but immediately interpreted. He is told that he distrusts "his parents because he wished to blow them up with his 'big job' as well as to poison them with his urine, both of which were felt to be poisonous when he hated his parents. Therefore he expected them to do the same to him." The therapist does not bother to find out whether this was an occasional fear, a vague suspicion or a true delusion. We are not told whether this symptom disappeared.

Some of the drawings might make one think that this was a case of schizophrenia. However, the child's productions are so severely distorted by interpretations, that it is impossible to evaluate them. During session 17 the child draws a starfish inside a circle. Here is Melanie Klein's interpretation: "The big starfish also seemed to represent Daddy's devoured genital which made her (mother) bleed because it ate her inside; this was shown by the red border round the starfish. The starfish also stood for the greedy and frustrated baby—himself—injuring and eating Mummy's inside when he wanted her and she did not come." It is not surprising that the drawings following this one appear more and more abnormal.

I feel that one is justified in saying that the enormous emphasis on sexual interpretations must lead to sexual overstimulation of the child and amounts to a seduction. Richard came from a British upper-class home, and sex was not something natural and familiar to him. The author states that she had to "introduce in the course of the analysis certain terms which were unknown to him, such as 'genital,' 'potent,' 'sexual relations,' or 'sexual intercourse.'" She does not say whether she ever explained the anatomic facts to him about which so many children are confused. This in itself can cause anxiety and hypochondriasis. She assumes that he has an "unconscious knowledge of the differences between the sexes" when he complains as late as the 78th session that he does not know what a woman's genital looks like. In the 65th and 83rd sessions he makes a drawing of Melanie Klein and gives her a penis. One does not know whether this is due to lack of knowledge of the anatomy, whether it is in response to her suggestions or whether it really is, as she maintains, an expression of his unconscious.

The patient is told in the very first session when he talks about Hitler, that he does not really mean Hitler but "that Hitler was in a

way ill-treating his own people (the Austrians), including Mrs. K., just as the bad Daddy would ill-treat Mummy." When in the 5th session he shows anxiety and walks around the room, he is given the following interpretation: "This exploring the room stood for the wish to explore her (Mrs. K.'s) inside—due to his anxiety to find out whether there was a Hitler penis in it or a good one." In the same session he looked at a post card with a robin on it. This leads to the interpretation "that the robin stood for the good penis, also for a baby, and that he wished to make babies and to replace Mr. K. and Daddy." The child's world is sexualized, and what he sees and does consists of symbols standing for sexual fantasies, some of them so abnormal that they are only observed in psychotic patients.

The so-called transference relationship, in this case the relationship of a child to an adult, created by this approach is revealed in this scene from the 77th session: "He asked what would he do with Mrs. K. if he were in bed with her? Mrs. K. suggested that he should say what he thought he would do. Richard (shyly) said that he would put his arms around her, he would cuddle her and get quite close to her. After a pause, he said he did not think he would wish to do anything with his genital with her. From the expression on his face it was obvious that this thought was predominantly unpleasant and frightening to him." It seems to me that we as therapists should stand by the basic principle: *nil nocere*. No adult should under any conditions ever permit his relationship with a child to develop in a way which so obviously is dangerous for the child's mental health.

There is in this as in Klein's other books no convincing scientific evidence for her theories. Nevertheless, they have had a wide influence, not only in the field of child psychiatry, but also on child rearing and education. *Narrative of a Child Analysis* should therefore be read by everyone involved with the treatment of children.

HILDE L. MOSSE, M.D.,
New York City.

HYSTERIA, REFLEX AND INSTINCT. By Ernst Kretschmer. (New York: Philosophical Library, 1960, pp. 162.)

The author, who is primarily associated with the study of "body types" and their relation to behavior (1921), is also the author of many other important psychological studies. This book appeared in its original German in 1918, in Stuttgart, Germany.

To the author hysteria is not simply a clinical condition, but a pattern of reaction. Hoche stated in 1902 that under sufficient stress, everyone is susceptible to hysteria. Gaupp considers hysteria "an abnormal manner of reacting to the demands of life." Most authors agree that even the physical manifestations are psychogenic.

Hysterical reactions aim subconsciously to avoid facing threatening situations. Like an "instinctive flurry," it is a built-in mechanism with a biological function. The resulting initial movements are almost wholly mechanical. This is the "primitive" pattern. But in mature persons the pattern is deliberate and moves from without to within.

First comes the *panick* that paralyzes the higher mental functions. Frightened people scream, tremble, suffer spasms and convulsions and run around wildly and aimlessly. Among children this period is not followed by reflective speech, but by rapid pushing, jerking and screaming. Between these two reactions stand the hysterical hyperkinesias, fugues and convulsive paroxysms. The hysterical attack provides a remarkable example of an atavistic instinctive "flurry." Such reactions are safety valves for excessive psychic pressure in defective constitutions. The hysterical hyperkinesias and flurries may be observed in animals and among children in times of panic. It is a defense reaction that results in an involuntary motor discharge. The instinctive reaction travels on the lower pathway, while the higher pathway is that of selective and deliberate behavior. The hysterical reaction bears the same relation to normal behavior as does instinct to the intellect.

Kretschmer discusses the "death feint" (immobilization reflex) which bears a close relation to cataleptic and hypnotic phenomena. Surveying the behavior of animals, children, primitive tribes, mentally retarded, neuropsychotics and normals in times of stress, he finds that their reactions differ only by degrees. He achieved a great simplification and elucidation of the concepts of hysteria, reflex and instinct.

HIRSCH L. GORDON, M.D.,
New York, N. Y.

HISTORY OF PSYCHOLOGY AND PSYCHIATRY. By A. A. Roback. (New York: Philosophical Library, 422 pp. incl. indexes, illus., 1961. \$7.50.)

The author states his purpose to describe "the milestones in the progress of the mental sciences." He has selected some 150 names,

only a few of those still living being included, of chief contributors, outlines their work, together with brief biographical data. Individual items may run from a half page (Thomas Aquinas) to five pages (Freud). There are however many cross-references, occasionally erroneous. Important schools and movements are also discussed. Apt quotations from many of the subjects add value to the work.

Beginning with Aristotle and Plato, the book ends with Yerkes. Following the two major divisions indicated in the title, there are short sections dealing with educational psychology, tests and measurements, collective psychology and animal psychology.

There is much valuable information packed in this little book that must have cost much time to collect. It makes no pretense to being a full history, but it covers wide ground and for quick reference should prove very useful.

C. B. F.

THE PSYCHOLOGY OF CHARACTER DEVELOPMENT. By Robert F. Peck, with Robert J. Havighurst, et al. (New York: John Wiley & Sons, 1960, pp. xix + 267. \$6.50.)

The title is ambitious. Its treatment unites character with morality, which makes for some confusion. The earlier Character Education Enquiry of Hartshorne, May and Shuttleworth (which led to the conclusion of specificity in moral behaviour, and the ineffectiveness of character-building agencies) is challenged (by mode of experimental approach and by the "all-of-a-piece" concept of character-structure) by the current volume, with Havighurst's Prairie City research programme somewhere in the background of character study.

The data on which the report is based include the results of sociological community studies, individual case-histories, projective methods applied to young and old, family studies, and historical assessments of cultural attitudes to character formation in the individual. There emerges a concept of consistency-in-character even in inconsistency-of-behaviour.

The theoretical delineation is confused—inevitably so since character is depicted as a behavioural product in the individual, conditioned by culture, even where culture is symbolized by the accidental mores of conventional control, is so far as these can be identified as "morality." Psychiatry and its superimposed demand upon projective psychology are in part responsible for this confusion.

We still await a culture-free conception of character, whether in the young child or his

elders. The reviewer thinks this worth searching for, and waiting for. The reviewer's bias is towards a developmental psychological approach.

The volume is very worthwhile but, in the main, unconvincing. It raises more systematic problems than it solves.

W. LINE,
University of Toronto.

BIBLIOGRAPHY OF MEDICAL REVIEWS. Vol. 6. Cumulation. 1955-61. (Washington : U. S. Department of Health, Education and Welfare, Public Health Service, 1961, pp. 436.)

This volume supercedes the annual volumes published during the past five years and lists 3,300 review articles from the 1960 literature which will not appear separately. The style of entry used is that of the *Index Medicus*. It reports those papers which represent the survey, evaluation and synthesis of newly published information on thousands of topics of interest to biomedical research and to the practice of the health sciences.

It is a most valuable reference for medical libraries and cannot be too strongly recommended to assist in the problems of reference work.

JOAN M. W. JOHNSTONE,
Librarian,
Academy of Medicine, Toronto.

PROGRESS IN CLINICAL PSYCHOLOGY. Volume IV. Edited by L. E. Abt, and B. F. Riess. (New York : Grune & Stratton, 1960, pp. 181.)

In a highly selective and uneven fashion, the present volume purports to cover developments in clinical psychology for the years 1958 and 1959.

Three familiar figures in psychology present their views in their special areas of interest at this time. Carl Rogers appraising research in psychotherapy, much of which he himself has stimulated, finds evidence of steady growth in our understanding of the processes involved in giving help. He offers evidence that suggests a growing convergence of principles among the various schools of psychotherapy. Hans Eysenck sets forth in brief form a state-

ment of his position on diagnosis and behavioral therapy. O. H. Mowrer reiterates without elaboration or improvement his earlier challenging conception of the model of neurosis.

A brief and pointed review of the experimental problems associated with stress and adaptation investigations is offered by Lazarus and Riess. Some of the other areas examined are those of school psychology, group psychotherapy and psychoanalytic theory. The papers on these topics wittingly or unwittingly reflect the perplexity presently characterizing these fields. M. A. White, in a broad but sensitive assessment of psychology in schools, outlines the professional issues currently seeking resolution.

Among the remaining chapters, one of which has questionable membership in this volume, *viz.*, "Psychoanalysis and Literature" by H. Slochower, two chapters invite special comment. A workmanlike review of the research literature on hypnosis has been contributed by Milton Kline. This paper, together with an earlier paper by J. M. Schneck in Volume II of this series, constitute a valuable review of a neglected but lively field.

A particularly provocative paper has been prepared by Gregory Razran setting out a series of Russian experiments on interoceptive conditioning. These experiments in which either the conditioned stimulus or the unconditioned stimulus, or both, are delivered directly to the mucosa of a specific viscus, reveal powerful properties of learning in this realm.

While only a very restricted range of stimuli have been investigated, the unconscious, continuous, and behaviorally potent character of visceral conditioning commands clinical and research interest. Although the discussion of these investigations for psychoanalytic and psychosomatic theory are only briefly discussed, the perspectives revealed are clear and exciting.

Despite its shortcomings as a rounded statement of progress in clinical psychology, many will find particularly useful or interesting chapters which recommend the acquisition of this book.

NAVY PSYCHIATRIC ASSESSMENT PROGRAM IN THE ANTARCTIC^{1, 2}

J. E. NARDINI, CAPT. (MC) USN, R. S. HERRMANN, CDR. (MSC) USN,³
AND J. E. RASMUSSEN, CDR. (MSC) USN⁴

The International Geophysical Year, 1957-1958, produced a research endeavor of heretofore unequalled magnitude. One part of this gigantic undertaking was the participation of the United States in large scale basic science studies aimed at increasing man's knowledge of the Antarctic. Seven bases were established in Antarctica in connection with this effort. While the scientific program was almost exclusively the responsibility of civilian investigators connected with the IGY, logistic support for the scientific personnel was provided by the United States Navy. The program was considerably reduced in scope following the International Geophysical Year; however, it has been continued to the present time under the sponsorship of the National Science Foundation and the National Research Council. The Navy's role in providing logistic support has remained essentially unchanged.

It has been the Navy's responsibility to transport the scientists and their equipment both to and within the Antarctic, to construct as well as maintain the bases and equipment, and to provide the medical, dental, and commissary services required for what might be considered 7 small communities. All the bases are totally independent and isolated from one another, as well as from the outside world, for approximately 6-8 months. Even radio communication occasionally is cut off due to unfavorable weather conditions.

During the year immediately preceding the IGY, the Navy undertook the establishment of the initial Antarctic bases. This expedition was marked by an untoward event in that one man developed a frank and florid psychosis. As might be anticipated, the ensuing management problems were of considerable magnitude inasmuch as there were no provisions for adequately separating such a patient from the remainder of the group, and it was impossible to evacuate him from the Antarctic.

As a result of this incident, the Bureau of Medicine and Surgery was requested to undertake a neuropsychiatric assessment of all personnel, military and civilian, who were scheduled to winter over during the International Geophysical Year as well as during the subsequent expeditions. It was necessary to begin the psychiatric assessment program on approximately 6 weeks notice; however, in spite of the pressure of operational commitments, an effort was made to approach the task both from a research and a clinical standpoint. The research endeavor has been devoted to developing criteria for psychiatric selection as well as identifying psychological variables influencing performance in such extreme isolation. Because of unforeseen and at times overwhelming difficulties in the collection of data on human behavior in the Antarctic, our fund of objective information in this area has accumulated quite slowly. Nevertheless, we have now learned a great deal about the psychiatric aspects of military duty in such extreme isolation.

The present paper is limited to summarizing the results of the psychiatric assessment procedure with particular emphasis on small stations. Certain personality traits or characteristics which appear to be of significance in successful adjustment in the geographically isolated and stressful en-

¹ Read at the 117th annual meeting of The American Psychiatric Association, Chicago, Ill., May 8-12, 1961.

vironment of the small station in the Antarctic will also be presented.

This research is not the product of any single individual's effort. While the data were collected by many persons, the bulk of the data analysis was accomplished by the staff of the U. S. Navy Medical Neuropsychiatric Research Unit, San Diego, California.⁵

SUBJECTS

The personnel assigned to duty in the Antarctic program constitute a somewhat different population from that usually encountered in Navy psychiatric selection programs. All men wintering over on Operation Deep Freeze are volunteers in the true sense of the word. None of the military personnel is a recruit, and the civilian personnel are all trained in some scientific or technical specialty.

The distributions for age and length of service of the military personnel assessed for the 1960-1961 Deep Freeze program are presented in Table I. It is interesting to note that over half of the men are 25 years of age or older and almost 50% have over 6 years of service.

The personnel are initially selected on the basis of their possessing military or civilian specialty training which qualifies them to perform a clearly defined job in the Antarctic. Inasmuch as the administrative selection is accomplished prior to the psychiatric assessment, all persons undergoing the psychiatric and psychological examination are known to possess sufficient emotional stability, personal adequacy and intellectual capacity to have attained and demonstrated a satisfactory degree of proficiency in their vocational endeavors. Moreover, all of the military personnel have survived the psychiatric assessment program at the recruit level. Thus, in one sense, there is some degree of psychiatric selection operating in the administrative selection of personnel.

Evaluation Procedure. All personnel, military and civilian, are subjected to essentially the same assessment procedures although the examinations are carried out at a number of different Navy activities. In addition to various attitude scales and psychological tests which are administered as part of the program of studying group function and interaction during the period of isolation, each man is required to complete an extensive biographical inventory.

Following the group testing procedure, each man is seen in an unstructured psychiatric interview. While the length of the interview was determined by the psychiatrist, a maximum of one hour is scheduled for this purpose. In most cases the interview is completed in approximately 30 minutes; however, this time is occasionally exceeded when questionable cases are encountered. The completed biographical inventory is available to the psychiatrist at the time of interview and is used to obtain a rapid appraisal of areas in the individual's past personal history which might be worthy of some careful exploration. At the completion of the interview, the psychiatrist is requested to complete a form in which he summarizes the results of his examination and makes a rating on a 5-point scale as to the man's suitability for duty in the Antarctic.

Each man also is seen by a clinical psychologist who administers a Rorschach test and summarizes his findings on the same

⁵ Among those persons who made an extensive contribution to the research effort are: Drs. H. Zimmer, J. H. Rohrer, W. L. Wilkins, E. K. E. Gunderson, P. Nelson, and J. A. Rose.

form used to record the results of the psychiatric examination. The psychologist also rates each man in terms of his suitability for Antarctic duty.* Upon completion of the individual assessments, the psychologist and psychiatrist who had conducted the examinations meet as a team and make a final appraisal of the subject which is based on a joint consideration of their individual findings. The final team rating, which often differs from the rating assigned by either of the examiners, is used as a basis for the formal recommendation as to the subject's psychiatric suitability for Antarctic duty.

Assessment Criteria. In any operational program of this nature, the isolation of objective criteria for use in making a psychiatric and psychological assessment constitutes a perennial methodological problem of major proportions.

Because of operational requirements that psychiatric assessment programs be undertaken on short notice, it was not possible to conduct preliminary studies which would yield even crude criterion information. After a search of the limited literature which was available, a decision was made to focus upon 4 primary areas in determination of psychiatric suitability for the Antarctic program. These areas were: motivation, history of past personal effectiveness, present ego strength and adequacy of defense mechanisms, and finally adequacy of interpersonal relationships. Thus, individuals who showed no obvious defects or weaknesses in these 4 areas were considered sufficiently stable to adjust in the Antarctic—or for that matter for almost any program of this nature.

In assessing the 4 areas outlined above, the clinicians were requested to focus on the adequacy of the individual's present and past motivation and functioning rather than attempt to predict what would happen at some time in the future in an essentially unknown situation. As a rationale for this procedure, it was considered that, other factors being equal, an individual who demonstrates evidence of adequate or healthy motivation and personality integration will continue to function effectively in the future.

The clinician's past experience in Navy neuropsychiatry was used as a frame of

reference for arriving at a determination of what constitutes an "average" rating on the 5-point scale of suitability. It was possible, therefore, to avoid speculating during the early stages of the assessment program as to the nature of the specific stresses of Antarctic isolation. In essence, this follows the "actuarial" approach to clinical judgment so lucidly discussed by Hunt(1). Fortunately, Navy psychiatrists and clinical psychologists have an opportunity to see large numbers of relatively stable individuals, a factor which aids in forming an adequate frame of reference for the assessment procedure.

Subsequent to the first year, the assessment criteria have undergone a continual refinement. This has been done primarily on the basis of information obtained during debriefing interviews with wintering-over personnel, such as those conducted by Rohrer(3, 4) and Mullin, *et al.*(2). However, it is interesting to note that 4 areas which were initially given greatest weight in the assessment procedure have remained unchanged. The subsequent refinements have consisted of adding more detailed information as to the pertinent variables in each of these areas. The nature of these refinements will be the section on results.

Follow-up Data. The complexity of collecting follow-up data in this situation is astounding and at times extremely frustrating. On occasion the forms for recording the information have been lost or destroyed in transit before the wintering-over period began. On other occasions, the pressure of a 16-hour work day precluded the collection of data in accordance with the prearranged schedule. However, in spite of these difficulties, information on the incidence of serious psychiatric disturbances has been obtained from all stations. Moreover, follow-up information concerning actual performance has been obtained on 10 small stations as well as 2 of the larger stations.

Four sources of criterion data were built into the research design: peer nominations, supervisor performance ratings, medical symptom check lists, and debriefing interviews with personnel at the completion of their wintering-over experience. The peer nomination technique generally proved to

be so psychologically threatening that it was discontinued as a routine technique. The symptom check lists yielded very little information on the group as a whole. However, the supervisor performance ratings, combined with information obtained from the interviews, present a relatively clear although gross picture as to the adequacy of each individual's psychiatric functioning during the wintering-over period. The officers-in-charge of the stations were responsible for collection of the ratings which were obtained during the wintering-over period.

RESULTS

Incidence of Psychiatric Disorders. During the 5 years covered by the present program, there have been no documented cases of psychiatric illness, which clearly reached psychotic proportions, among the wintering-over personnel. Of the 6 men formally admitted to the sick list, only one had been through the psychiatric assessment procedures. This case was diagnosed as an emotional instability reaction. The remaining 5 men had been selected as last minute replacements for individuals who dropped out of the program for a variety of administrative reasons. Their diagnoses included 3 cases of relatively severe neurotic depression and 2 of anxiety reaction.

While the above data would indicate that the assessment program generally has been successful, it should not be construed as implying that there has been a complete absence of psychiatric disturbances in the Antarctic. Information obtained through debriefing interviews clearly indicates that acute emotional disturbances are not uncommon. This is particularly true at the smaller stations, comprised of 15-40 men. There also is reason to believe that several men may have experienced brief near psychotic episodes. Examples of such incidents are reported by Rohrer(3). Although these psychiatric problems may not be of sufficient magnitude to necessitate admission to the sick list or formal medical treatment, on occasion they create extremely tense and stressful situations for the remainder of the station personnel. With a few isolated exceptions, the groups appear to have spontaneously responded to the acute emotional disturbances with tech-

niques which closely resemble those of the classical therapeutic community.

Low grade depressions are prevalent during the 3-month period of darkness. Headaches which appear to be of psychogenic origin are frequently reported. While acute anxiety attacks are occasionally reported, these are relatively uncommon and usually related to specific situational factors beyond the individual's control. Not a single case of psychosexual disturbance or overt homosexual activity has been reported during the 5 years of the study. The functional backaches and gastrointestinal complaints so commonly found in the military services have rarely been observed among the wintering-over personnel. However, this is not surprising in view of the highly select nature of the population.

Relationship of Psychiatric Assessment to Performance. The assessment program has been successful in identifying and eliminating those individuals who will become totally ineffective under the stress of Antarctic isolation, or will require hospitalization for a psychiatric disorder, but it has been less effective in predicting precise levels of performance. While this finding certainly would be expected in view of the history of psychiatric assessment programs in general, the results nevertheless do show a significant positive correlation between prediction and performance.

Two separate approaches have been made to analyzing the relationship of psychiatric prediction and performance effectiveness. First, the performance of the military personnel at each of the 10 small stations was evaluated on the basis of supervisory ratings.⁶ Secondly, the predictions were studied in terms of men falling at either extreme of the performance continuum.⁷

Because the evaluations of Antarctic adjustment were based on gross factors rather than precise measures, broad categories of

⁶ Analysis of this portion of the research data was made by Dr. E. K. E. Gunderson and Lt. P. Nelson (MSC) USN, at the U. S. Navy Medical Neuropsychiatric Research Unit, San Diego, Calif.

⁷ This analysis was undertaken by Dr. J. H. Rohrer, Georgetown University School of Medicine, using data which he and Capt. C. S. Mullin (MC) USN collected through debriefing interviews in the Antarctic.

performance effectiveness were used. In analysis of the predictions in terms of supervisor performance ratings, subjects in each group were classified "high" or "low" in performance (upper half or lower half of the group), on the basis of independent rankings by 2 clinicians. In only one case was there more than one disagreement between the 2 clinicians on the categorization of subjects in a given group. The differences were resolved through use of additional information, such as that obtained from the debriefing interviews. It should be noted that the splitting of each group into an upper and a lower performance category, with an equal number of subjects in each, does not imply that all of the subjects in the lower performance category were unsatisfactory or ineffective during the wintering-over period. On the contrary, the vast majority of the men in the latter category did serve satisfactorily.

Table 2 includes ratings made on men at 6 of the stations. These stations were con-

sidered together because the subjects were rated on one form of the psychiatric rating scale (ratings from 1 to 5), while the men at the 4 stations included in Table 3 were rated on a different scale (ratings from A to E). On the first scale, a rating of 3 was interpreted as "average"; a rating of C on the second scale indicated "can't decide whether superior or inferior." Because of a possible difference in examiner orientation, the data were summarized separately.

The tables indicate fairly substantial predictive validity for the psychiatric ratings at either end of the performance scale. The degree of relationship is shown, roughly, by the tetrachoric correlations of .41 and .66 which are statistically significant in spite of the unequal distributions for the dichotomized prediction categories.

Table 2 discloses the predictions of superior or outstanding performance to have been more valid for the Deep Freeze 1957 and 1960, while during Deep Freeze 1958 the reverse was true, and the predictions of

Proportion falling in High Performance Category		.17	.59		
$r_t = .66$					

Quite possibly, the difference in terminology on the psychiatric assessment rating scales had a significant influence. On the other hand, these results may be attributable to the fact that a different group of examiners is used each year in the assessment program. This latter factor becomes important in view of the varying levels of training and experience of the psychiatrists and psychologists who served as examiners. Generally speaking, the psychiatrists' training ranged from the first year residency level through board certification with 10 years of clinical experience. The clinical psychologists' training ranged from one year of graduate school through the Ph.D. level with 15 years of experience.

In view of the small number of subjects involved, it was considered inappropriate to attempt more detailed statistical treatment of these data. However, it is extremely interesting to note that station number 4 (Table 2) is the only one of the 10 stations at which over half of the personnel were considered to be psychiatrically inferior on the basis of initial assessment. This particu-

lar group during the wintering-over period were, without a doubt, far more extreme than those which have been experienced by any other group of men during the 5-year history of Operation Deep Freeze. Secondly, the medical officer assigned to this station was the only one among the 10 physicians to consider the psychiatric assessment program totally ineffective.

Rohrer approached the question of assessment validity by studying the 2 extremes of the performance continuum. Through a review of the debriefing information which he and Mullin had collected during their visits to the Antarctic, 6 men were selected on the basis of having made the most successful adjustment among the personnel at small stations during the wintering-over period. Six men also were selected as having made the least successful adjustment. A brief description of each man was prepared, including the factors which had contributed to the satisfactory and unsatisfactory adjustment. Once this had been accomplished, the original assessment records were obtained and reviewed to check the validity of the

assessment predictions. This work is reported in detail elsewhere(4). However, it should be noted that among the men performing most successfully, 3 were rated as superior and 3 as above average on the initial assessment. Among the least successful men, 2 were rated as inferior, 2 were rated as average bordering on inferior, and 2 were rated as average.

Obviously, these results cannot be interpreted as demonstrating that the assessment procedures yield accurate predictions of effectiveness under conditions of Antarctic isolation. Rather, the data are considered to constitute positive and encouraging benchmarks for the development of further criteria. Certainly, the results are sufficiently positive to warrant continuation of the program and further refinement of the assessment procedure.

Revised Screening Criteria. Through a process of repeatedly postulating the importance of specific motivational factors and personality characteristics, and constantly revising the conceptual formulations through debriefing interviews, it has been possible to gradually focus on what appear to be the more significant variables in adjustment to Antarctic isolation. Obviously, there is no one personality pattern which ideally suits an individual for assignment to a program such as Operation Deep Freeze. However, a number of positive and negative characteristics have been isolated during the past 5 years which now appear to be important in the psychiatric assessment of personnel for this duty. They are briefly summarized below.

Motivation. Positive motivation for Antarctic duty is not given as much weight as it was at one time in the assessment program. Many of the most successful men are not really sure why they volunteer. Among the more positive motivations are: save money, possible advancement in rate, and the challenge of an unusual experience. Unhealthy motivations, which on the basis of past experience are cause for disqualification, include the following: escape from marital conflict, transfer from an undesirable duty station, and immature search for adventure. Parenthetically, it should be noted that Antarctic duty is now mostly hard work, little adventure, and rather

plush living accommodations.

History of Past Personal Effectiveness. This variable has come to be considered one of the most important in the assessment of Deep Freeze personnel. Each man in the wintering-over party has a specific job which he must perform. In one sense, every man at a small station is dependent on every other man. Status is determined primarily by vocational effectiveness. The man who is not technically competent is both a source of threat to the well-being of the group and a source of interpersonal conflict. The technically competent individual may display considerable psychopathology during the wintering-over period and still be effective. However, the same degree of psychopathology in a man with less technical competence would render him ineffective. Under the heading of work effectiveness, one must include responsibility and dependability as well as technical competence. A history of ineffectiveness in vocational performance or inadequate training for the job to which a man will be assigned are clear reasons for disqualification.

Ego Strength and Adequacy of Defense Mechanisms. Any evidence of potential for emotional decompensation, or history which is suggestive of possible decompensation during periods of stress in the past, is considered disqualifying. At the present time, much greater emphasis is placed on adequacy of defense mechanisms than upon the nature of the mechanism. Thus, clear-cut neurotic mechanisms, even though they may border on the pathological, are not in and of themselves considered disqualifying. In this connection, there has been a shift in attitude toward psychopathology during the time the assessment program has been in operation. The only neurotic mechanism which is now considered clearly disqualifying is that of extreme rigidity. Experience has shown that the rigid individual who maintains ego integrity by adherence to fixed beliefs or routines without ability to be flexible in the face of group needs invariably becomes a source of disruption to the group during the wintering over. Although not originally considered to be of any particular significance, personality disorders have been found to constitute a rather serious problem. Demanding, sensi-

tive, narcissistic individuals invariably are a constant source of friction and a demoralizing influence to personnel at small stations. On the other hand, individuals manifesting evidence of personality disorder adjust reasonably well at larger Antarctic stations where there is a lesser degree of enforced interpersonal contact.

Group Structure. While work efficiency now might be considered the most important variable in Antarctic adjustment, the structure of the small isolated group has come to be considered a close second. Because of operational demands in the recruiting and training of personnel, little attention has been given to this factor in the assessment program. However, it is now clear that the greatest future gains in the preventive psychiatry aspects of the assessment procedure will be found in evaluating the individual in terms of the group to which he will be assigned. Advances in this area will make heavy demands upon the theory and techniques of social psychology. It is anticipated that a large portion of future research effort will be devoted to the development of criterion measures of small group effectiveness in the Antarctic and methods for structuring such groups.

SUMMARY

The Navy program for psychiatric assessment of personnel wintering over in the Antarctic has been described. During the 5-year history of the assessment program, there have been no documented cases of psychotic illness. Six men have been admitted to the sick list for psychiatric reasons, only one of whom had been through the assessment procedure. This case was diagnosed as a personality disorder. Thus, it would appear that the program has been effective in identifying and eliminating individuals who will develop serious or incapacitating emotional illnesses under the stress of isolation.

An analysis of data relating to performance effectiveness in the Antarctic shows that there is a significant positive correlation between the initial psychiatric prediction and subsequent performance. However, because of several limitations in the data, the results in this aspect of the study should be interpreted with caution.

Certain shifts have occurred in the assessment criteria during the past 5 years. The most important variable in adjustment to Antarctic isolation now is considered to be vocational effectiveness. The structure and composition of the small isolated group is next in importance. Except for extreme rigidity, there are no neurotic mechanisms which are considered, *per se*, to be disqualifying. However, personality disorders do constitute a rather serious problem.

DISCUSSION

EUGENE ZISKIND, M.D. (Los Angeles, Calif.). —I have nothing but commendation for this paper of Capt. Nardini and his colleagues. The facts speak for themselves. The program has selected 1000 normal or superior, successfully screened individuals so that not a single major psychiatric casualty occurred during the stress of Antarctic isolation—an enviable record for even less stressful ways of living. No controls were possible. Perhaps a clue as to what such controls might have shown is to be gleaned from the fact that 5 of the 6 men who appeared on the sick list came from the small number who were not screened.

A recent article in *Science*, "Rationalism versus Empiricism in Cosmology," includes the statement, "The temptation to substitute logic for observation is particularly hard to resist in astronomy." How much more is this true for the behavioral sciences. Yet the authors did resist this temptation as shown by their hard headed common sense empiric approach throughout their study.

I assume I was chosen discussant because of my experiences in so-called "sensory depriva-

tion." This leads me to make a few comments related to the second goal of this study, which was to ascertain factors that might interfere with the efficiency of personal performance. The authors mention that in stations of 100 men tensions are minimal, but that in smaller groups of 15-40 problems appear. One would expect that in isolation of the single individual under these conditions the stress would be much greater and approximate that of sensory deprivation experiments. Experiences in the Antarctic might be analogous to the sensory deprivation situations known to jet pilots, long distance night truck drivers and radar sentinels exposed to little external stimulation.

Be that as it may there are many similarities between sensory deprivation and isolation, although the two are, of course, not interchangeable. Yet in extreme instances—and frequently in moderate ones also—sensory deprivation and isolation are concomitants and cannot be separated. In fact herein lies one of the major obstacles to progress in sensory deprivation research. In neither sensory deprivation nor isolation is the stressor unitary but consists of admixtures of multiple factors. The variables from study to study are so great that it would be well to insist on operational definitions. Furthermore, the resulting symptoms have not been clearly defined, making adequate comparisons difficult.

Besides these limitations which sensory deprivation and isolation have in common, the limits of stress for each are as yet unknown. What is the least amount of sensory deprivation or isolation that can produce symptoms and what is the greatest degree of either that can be tolerated without producing symptoms? It was the evidence of Hebb and his group that all individuals who remained in the ex-

perimental isolation chamber for 3 days had hallucinations which pointed to a universal vulnerability. It would be helpful therefore to differentiate the amount of sensory deprivation which causes symptoms universally and also that which indicates the further limits of individual vulnerability. These items give only a partial picture of the complexity of sensory deprivation research of the individual subject in a controlled experimental environment. How much more complicated are the field studies of Antarctic isolation where many of these considerations also apply, but where one has additional factors related to the small group with less isolation and much less readily identifiable variables. The authors have elsewhere referred to the large number of unanswered problems.

One final reference related to their recognition of the need for knowledge from the field of social psychology in the form of 2 questions: 1. Would the inclusion in the team of investigators of other social scientists with their field techniques (*e.g.*, the sociologist and anthropologist) have any merit? 2. Would the inclusion of participant observers in some of the stations be warranted, as a more definitive way of settling the value of such procedure?

Let me close by saying that it is to the everlasting credit of the authors that under the limitations of short notice and a distant arduous environment calling for the taking out of one or more years of the lives of professional volunteers they still rigged such a well conducted research into what was primarily a practical assignment. These investigators have the privilege of evaluating a military and scientific experiment in nature with great implications for psychiatry. They have already shown such scientific perspicacity that we shall look forward with avid interest to their future reports.

THE COURSE AND OUTCOME OF PSEUDONEUROTIC SCHIZOPHRENIA¹

P. H. HOCH, M.D.,² J. P. CATTELL, M.D.,³ M. O. STRAHL, M.D.,⁴
AND H. H. PENNES, M.D.

There are few reports of the history and treatment of patients with pseudoneurotic schizophrenia, usually confined to one or a small number of cases (1, 2). There are no studies of the course of the illness with post-treatment follow-up investigations. Many psychiatrists are interested in what happens to these patients during therapy and after they leave treatment. Do they sustain the gains achieved? Do they relapse and again become dominated by pseudoneurotic symptoms or do they develop classical schizophrenic reactions? What kinds of treatment are associated with what course and outcome?

METHOD

The course of the illnesses of 109 patients was followed for a period of 5-20 years. It is convenient to consider these patients in two groups: Group 1: 45 patients treated in clinics or private practice by one of us and subsequently interviewed 5-15 years later. A few were being cared for by other psychiatrists at the time of the follow-up study. Detailed reports were obtained from these psychiatrists. Group 2: 64 patients who had been hospitalized at Psychiatric Institute, most of them known to at least one of us at the time of initial admission or during subsequent admissions. Of these, 34 were interviewed by one or more of us 5-20 years after the patient was originally admitted. The other 30 patients were not available for follow-up interview. However, more than two-thirds of this group had been hospitalized subsequently and one-fifth were in the hospital at the time of the follow-up study. Clinical summaries were

obtained from these hospitals. In addition, information was available through correspondence and telephone conversations with patients, relatives, and patients' psychiatrists.

A number of factors influence the collection of data in this type of follow-up study, and these must be considered in appraising the results. Only one-third of the patients, who were regarded as having a diagnosis of pseudoneurotic schizophrenia at the time of first admission to Psychiatric Institute, responded to our letter requesting an interview. A significant number of the letters were returned as undeliverable. Some patients wrote declining an interview, stating that they wished to repudiate any memories of past illness and hospitalization. This factor may have accounted for the failure of some to respond at all. Patients who came for interview volunteered for a variety of reasons: a wish to express gratitude for earlier treatment and provide information that might help others; a dramatization of triumph over past unpleasantness and fear; curiosity about the project; an effort to gain our appraisal of their mental health; a recognition of possibly needing treatment or a desperate plea for treatment. The majority of Group 1 patients responded and the data concerning them is more extensive.

The initial diagnosis of pseudoneurotic schizophrenia in these patients was based on finding a number of the primary clinical symptoms of pseudoneurotic schizophrenia and the secondary clinical symptoms of pan-anxiety, pan-neurosis and chaotic sexuality (3). Patients who had a history of overt schizophrenic reactions prior to initial admission to Psychiatric Institute or prior to beginning clinic or private treatment, were excluded from the study. At the time of the follow-up interview, often conducted by two or three of us, the patient's history preceding initial hospitalization was reviewed. If the diagnosis of pseudoneurotic schizophrenia could not be retrospectively con-

firmed, the patient was excluded from the series. Interval history was reviewed with attention to the patient's total life functioning. Evidence of an overt schizophrenic episode during the interval was carefully evaluated and the diagnosis was made according to the usual criteria, including data from hospital records if the patient had been hospitalized. An evaluation was made of the patient's current psychiatric status and of his functioning in all areas of behavior. On the basis of these data, we arrived at a psychiatric diagnosis and a comment on the patient's symptoms and his current functioning. We devised a 5-point rating scale as a convenient method of grouping the patients according to their level of health and functioning at the time of the follow-up interview. The following criteria were used:

1. Absence of manifest clinical symptomatology. Functioning adequately in all areas of behavior (domestic, social, occupational, sexual, intrapsychic).
2. Manifest symptoms few in number and mild in intensity. Functioning moderately adequate in all areas—or adequate in most areas and poor in a few areas.
3. Manifest symptoms moderate in number and intensity. Functioning moderately adequate in some areas—or poor in most areas and adequate in a few.
4. Manifest symptoms dominating the patient's life.

Functioning impaired in all areas. 5. Overt schizophrenic symptomatology. Functioning impaired in all areas.

This type of rating scale has many subjective components and its effectiveness depends on the skill and experience of the investigators who apply it and the communication among these investigators. The members of our group have been closely associated for more than a decade and have spent hundreds of hours studying and evaluating a large number of patients before, during and after various types of treatments and tests in clinical and research work. We have found this clinical method of evaluating patients superior to several types of allegedly objective and quantitative methods that we have tried. A series of concise statements about a particular patient provides a clearer picture than any of the behavior rating scales that we have used or seen.

RESULTS OF FOLLOW-UP INVESTIGATIONS

The distribution of patients according to sex, previous episodes of emotional illness, and age at time of initial contact is given in Table 1. Of the 109 patients studied, approximately half were men and half women. There was a slight preponderance of women in Group 1 and of men in Group 2.

TABLE 1

Distribution of Patients According to Sex, Previous Episodes of Emotional Illness, and Age at Time of Initial Contact

The actual age of onset of the illness is often difficult to determine and we gained the impression that many of the patients had had some disability most of their lives. Further information on this point will be presented at another time in a discussion of the development of pseudoneurotic schizophrenia. About 40% of the patients had a history of one or more previous episodes of emotional illness, only some of whom had had psychiatric treatment. The incidence of a history of previous episodes was lower in Group 1 (31%) than in Group 2 (42%). We regarded these episodes as earlier manifestations of the pseudoneurotic schizophrenia that we observed at the time of our initial contact.

The age of patients at the time they first came to the Psychiatric Institute or for treatment with one of us shows a striking cluster in the third and fourth decades of life. Almost 50% were in the 21-30 age-range and more than 25% in the 31-40 age-range. Pseudoneurotic schizophrenia does

occur in younger age groups, and at a higher incidence than our findings show (9%). Whether the diagnosis can be made in children under age 12 or 10 is a controversial issue. Bruch states that some of the evidences of disorders of thinking and associations, disorders of emotional regulation and of sensorimotor and autonomic functioning can be perceived in this age group if they are looked for (4). The same is true at the other end of the age spectrum. The 2 oldest patients in this survey were 56 at first contact. However, we have studied a number of older patients at the Psychiatric Institute, the eldest being a man of 69 who had apparently been suffering from pseudoneurotic schizophrenia for 50 years or more. He had been treated by numerous therapists and hospitals with many oscillations in the intensity and type of his symptomatology.

A survey of selected data on the subsequent course of these patients is presented in Table 2. The range of the follow-

† One patient: 40 months; one patient: 52 months; and 3 patients: 80 months.

‡ Patient began private treatment in 1950 and left in 1952. Two subsequent hospitalizations; ECT treatment. Committed suicide in 1954.

§ Patient at Psychiatric Institute in 1945 and again in 1946. Committed suicide in 1948.

up period was 5-20 years; average 9 years. There are two exceptions to the 5-20 year range; namely 2 patients who committed suicide 3 and 4 years respectively after initial contact and 2 years after final contact. There were no other deaths in this series of patients.

Some of the details about the incidence and duration of initial and subsequent hospitalization are summarized in Table 2. Following initial contact, whether at the Psychiatric Institute or in clinic and private practice, about two-fifths of the patients were hospitalized sometime during the follow-up period. There is a significant difference between the 10% of Group 1 and more than half of the patients in Group 2 who required such treatment. The number of hospitalizations after initial contact, the total time spent in the hospital and the number of hospitalized patients at the time of follow-up study were also greater for Group 2 than for Group 1 patients. In both groups, patients were inclined to seek repeated voluntary hospitalization and to leave against advice, though some were discharged prematurely or because they refused specific treatment. The incidence of legal commitment was higher in Group 2, some being committed when they developed overt schizophrenic episodes during voluntary hospitalization or shortly after eloping from a hospital. These data on hospitalization may be a commentary on the ambivalence of patients about accepting adequate treatment (including hospitalization or somatic treatment) and the ambivalence of some psychiatrists about the use of somatic treatments or hospitalization. Information about the treatment of these patients will be presented below.

Whether patients with pseudoneurotic schizophrenia ultimately develop overt schizophrenic symptomatology has been a controversial question for some time. That they do is a premise implicit in the use of such terms as latent, borderline and transitional which some workers employ to describe the pseudoneurotic syndrome(3). To our knowledge, there have been no definitive studies on this question, nor of related issues, such as the kinds of overt schizophrenic reactions that develop and the incidence of remissions. In our observations,

approximately 1 patient in 5 (20%) developed an overt schizophrenic episode and half of these (10%) had a remission. Thus, 10% who originally had the pseudoneurotic form of schizophrenia later developed chronic forms of schizophrenia with the classical catatonic, paranoid and occasionally hebephrenic symptomatology. We can speculate that appropriate treatment applied early enough might yield an even lower incidence of overt episodes and a greater frequency of remissions.

The development of overt schizophrenic symptomatology was more frequently gradual and insidious than sudden and abrupt. Catatonic and paranoid symptomatology were most frequently observed and, in some instances, there was acute excitement oscillating with stupor. In most instances, a diagnosis of schizophrenia, mixed type, was appropriate for purposes of record. It is generally recognized that those who have abrupt onset of florid symptomatology have a greater tendency to remission than those with insidious onset. There were instances of remission in patients with both types of onset in our material. The illnesses of some patients progressed insidiously, often despite adequate treatment, and signs of schizophrenic deterioration became manifest in a few.

Eleven of the patients were known to have attempted suicide sometime during the course of their illness. It may be more accurate to state that they took action that could seriously jeopardize their health and welfare, some instances of which occurred during hospitalization. Only 2 patients actually committed suicide. We regard this 10% incidence of attempted suicide and less than 2% actual suicide as a very low rate, particularly in view of the suffering that many of these patients experience.

The level of health and functioning of each patient was evaluated at the time of the follow-up investigation according to the rating scale described above. The incidence of the various ratings in the 3 groups of patients is recorded in Table 3. It must be noted that we were quite conservative in evaluating freedom from symptomatology and adequacy of functioning. We feel that some of the primary clinical symptomatology can be discovered in some patients

* Criteria for numerical ratings given in section above on methodology.

† For convenience of discussion, the numerical ratings of outcome at the time of follow-up evaluation have been consolidated as follows: Ratings of 1 and 2: Good; Fair; and ratings of 4 and 5: Poor. The percentages of patients in each group with Good, Fair and Poor outcomes are designated in the table. The percent distribution of outcome for all patients is also shown.

who appear to be functioning well. Reports of a patient's functioning, by a relative or himself, can be biased toward health. Careful clinical examination frequently can penetrate the façade and disclose some of the primary clinical symptoms.

Even those who derived a great deal of benefit from treatment, including positive alterations in character and a hitherto unachieved level of functioning in many areas, were regarded as still vulnerable to illness. Integrative capacity, threshold of anxiety response, reactive threshold to various stimuli and regulation of energy remained somewhat tenuous, though equilibrium was maintained much more easily and consistently than ever before. We have noted that these patients often have an irregular, oscillating course with frequent shifts in the leading symptomatology, variations in the intensity of anxiety and of the symptomatic defenses against it, as well as variable inhibition of functioning. Patients who had made solid gains through treatment and life experiences were observed to have what we term microscopic, rather than gross, oscillations—brief flurries instead of prolonged storms—from which there was often a rapid recovery. Such flurries were usually associated with some type of environmental vicissitude. The reaction was often recognized by the patient as being related to such stimuli, either immediately or in retrospective consideration.

Other patients, such as some of those rated 2, and many rated 3, had some secondary clinical symptomatology and some impairment of functioning. The oscillatory

pattern was more pronounced in their illnesses, though not as prominent as it had been earlier, when they were more seriously disabled. Patients rated 4 were dominated by symptoms and had a total or partial paralysis of functioning. The leading symptoms and functional incapacities might be different than those which had been observed initially, but the degree of impairment was the same as before.

These observations are given as an elaboration of the rating scale concept and our technique of applying it. A patient seen in follow-up interview might be in one or another phase of an oscillation at that time; for instance, not as well as he had been for some time. This might lead to a downgrading of the rating he is given, depending on the frequency and intensity of such slumps and our evaluation of his relative vulnerability to decompensation. One patient, who had recently achieved success as the "star of a Broadway smash-hit," was found to be functioning relatively well and to be essentially asymptomatic, in contrast to his condition at the time of initial contact 9 years earlier. We felt that this level of functioning was maintained, at least in part, by the situation of the moment and that symptoms could reappear if a stressful situation arose. Thus, he was rated 2 instead of 1, a conservative evaluation based on the recentness of the gains and the special circumstances attending them.

For convenience of discussion, we have consolidated the numerical ratings of the levels of health and functioning at the time of follow-up evaluation (hereafter termed

"outcome"). Ratings of 1 and 2 are designated as Good ; 3 : Fair, and 4 and 5 : Poor (Table 3). Roughly one-third of the 109 patients falls into each of the categories. However, there are notable differences in outcome between the two groups ; the Good and Poor outcomes in Group 1 (44% and 16%) are an approximate reversal of the distribution in Group 2 (Good : 19% and Poor : 39%). This finding was expected in view of the composition of the two groups, the Group 2 patients initially having sufficient disability to warrant hospitalization. It is noteworthy that patients in Group 1 and some of those in Group 2 did achieve a favorable level of functioning and freedom from symptoms. Seventy percent of all of the patients achieved some relief of suffering and some improvement in functioning, changes gratifying to them and to the community.

We have investigated some of the clinicodynamic factors that might have been associated with the achievement of good, fair and poor outcomes 5-20 years after onset of illness or beginning of treatment. The following were surveyed : family history of mental illness in the direct or collateral line ; unusual occurrences during pregnancy and delivery ; sibling position ; broken home on the basis of death, divorce or protracted illness of one of the parents ; socioeconomic hardship ; personality of parents ; patient's development and his reactions to himself and the environment in infancy, childhood, adolescence and adult life (including character structure) ; educational and occupational history ; age at onset of illness ; severity and type of precipitating factors ; type, intensity and oscillations or shifts in secondary clinical symptomatology ; psychiatric treatment—including number and duration of hospitalizations, as well as type and duration of treatment in and out of hospitals (psychoanalysis, psychotherapy, electroshock, medication, other) ; attempted evaluation of whether the appropriate treatment was selected at the right time ; and subsequent environmental occurrences during the follow-up period.

The relative reliability of observations on these factors is highly variable. For instance, if the patient's father had been in a state hospital during the patient's youth,

one has definite evidence of a positive history of mental illness in the family. In addition, one can probably conclude that there was attendant disruption of the domestic scene with the patient fatherless for a significant period of time. Evaluation of the environmental opportunities and vicissitudes in an intact home and the patient's reactions to these is a more difficult task and not subject to the kind of verification just mentioned. The patient's age at the time he finished school is easily determined but the age at which he became ill is often unclear. The conclusions reached in the evaluation of these clinical factors must be viewed in the light of relative reliability. Apparent correlation, or lack of it, between a given factor and the patient's level of health and functioning at the time of follow-up would, in turn, be influenced by these considerations. The method of selection of the patients and the size of the sample also can affect the results.

Though statistically significant conclusions cannot be reached, we felt that certain trends or indications of correlative relationships might be evident. These can have psychodynamic, therapeutic and prognostic connotations and can serve as indicators for subsequent research.

This investigation disclosed that there is a correlation between the outcome of the illness and some of the factors mentioned, such as the type of treatment administered, but no significant relationship between outcome and many of the other factors studied. As an illustration of the latter, 3 of these factors are considered in Table 4 : positive family history ; a history of a broken home in youth and previous episodes of mental illness. There was a high incidence of positive family history for the entire series (50%), but such a history did not adversely influence the possibility of a good outcome. The experience of a broken home in youth was relatively common (37%) among this group of patients. The incidence in Group 1 appears to be much higher than in Group 2. Even so, it has to be stated that the information concerning Group 2 was not as complete and reliable as that about Group 1, and further studies are necessary.

Thirty-eight percent of the patients had had previous episodes of mental illness.

TABLE 4

Relationships Between Outcome of Illness and Family History of Mental Illness, History of Broken Home in Youth, and Previous Episodes of Mental Illness, According to Group

	OUTCOME	GROUP 1 (%)	GROUP 2 (%)	TOTAL FOR GROUPS (%)
Positive family history	Good	56 *	41	50 *
	Fair	50	59	56
	Poor		40	40
	Total	53	48	50
Broken homes	Good	63	17	43
	Fair	56	17	39
	Poor	40	20	27
	Total	57	18	38
Previous episodes of mental illness	Good	20	25	21
	Fair	50	48	49
	Poor	14	44	38
	Total	31	41	38

* For instance, of the 20 patients in Group 1 (see Table 3), who had a good outcome, 56 percent of these had a positive history; or, of the 32 patients in both groups who had a good outcome, 50 percent had such a positive history.

About 20% of those with a good outcome had such a history, while the incidence was approximately twice that much for patients with a poor outcome and even higher for patients who had a fair outcome. The apparently positive correlation between good outcome and low incidence of previous episodes is consistent with daily clinical experience. The paradoxical finding of a higher incidence of previous illness for those with fair than those with poor outcome can be resolved by further studies of⁹ larger groups.

Scrutiny of relationships between many of the other factors mentioned and the outcome of illness leaves us with comparably inconclusive information. The type or form of manifest clinical symptoms, pan-anxiety, pan-neurosis and chaotic sexuality, was not found to be significantly related to the outcome of the illness. There was, however, a correlation between quantitative differences in symptoms and outcome. There were differences in the number and the intensity of Group 1 patients' symptoms and those in Group 2. The latter had a larger number and wider variety of symptoms present at a given time. The relative dominance of the symptoms in the patient's hour-to-hour living was greater and many areas of behavior were affected. Thus, the associated disability in functioning was greater in Group 2 patients than in Group 1. This fact is implicit in the composition of the groups.

Those who were in the hospital at the time of initial contact obviously were more disabled than those in Group 1, who were ambulatory and first seen in clinics or private treatment. Functioning in the former group was grossly impaired in most or all areas of behavior. The Group 1 patients, in contrast, had symptoms and disability, yet were continuing to function. The functioning was maintained through great effort and in spite of anxiety and symptomatic defenses against it. Only occasionally did the functioning bring any measure of satisfaction or increased self-esteem, yet the patients pursued their ordinary activities and remained out of hospitals.

Primary clinical symptoms of pseudoneurotic schizophrenia: disorders of thinking and associations, disorders of emotional regulation and disorders of sensorimotor and autonomic functioning(3) were present in both groups. Such symptomatology was much more prominent and more readily detectable in Group 2 patients than among those of Group 1. All of these quantitative differences were reflected in the response to treatment and the outcome of the illness. The greater the quantity of symptoms, the less favorable the reaction to treatment and the outcome of the illness. The quantitation of these differences is obviously a clinical method since no other satisfactory technique has been devised.

A survey of the type, intensity and dura-

tion of treatment which these patients received presents numerous, complex problems. Data as to what kind of treatment was given, when, for how long and for what symptomatology—is most difficult to tabulate and appraise in a group of 109 patients. Nevertheless, we have adopted the hypothesis that the outcome of the illness must be a commentary on the treatment experiences of the patient. A wide range of forms and techniques of treatment was given to the patients who had good, fair and poor outcomes. The selection and application of treatment was influenced by the facilities available; the training, experience and skill of the psychiatrist; a variety of external circumstances: social, economic and geographic; and the patient's willingness to accept what was offered.

All the patients were reported to have received some type of psychotherapy, but there was great variation in the frequency, intensity and duration of the treatment. Many patients received some type of medication (barbiturate and amphetamine derivatives), usually as an adjuvant to psychotherapy. Some patients were given electroconvulsive treatment, ambulatory or coma treatment with insulin or a combination of these. Since the major part of our study was concluded before the newer psychopharmacological agents were available, their use does not figure in this report. Comments on their value in more recent treatment experiences will be reported at another time.

The data on the outcome of pseudoneurotic schizophrenia (Table 3) represent the results of conglomerate treatments. It is useless to speculate on what might have happened under other, perhaps more favorable circumstances of care and treatment. We believe that there are definite indications for various types of inpatient and outpatient treatment of people with this illness, including criteria for hospitalization and discharge and for modifications in psychotherapeutic technique.

In appraising the course of the treatment of a number of the patients, we gained the impression that treatment had often been "too little" or "too late" or both. This deficit was usually related to some of the issues already mentioned. A patient can receive

only the treatment which the psychiatrist is able to give and which he, the patient, is willing to accept. Such acceptance by the patient can be related to the training and experience of the psychiatrist in proposing and administering a given regimen of treatment. The best treatment can be given by a psychiatrist who is familiar with the psychodynamic frames of reference in psychotherapy and with the efficacy and use of somatic therapies. Especially important is a familiarity with the use of the newer pharmacological agents in conjunction with appropriate psychological treatment of these patients. One-sided approaches, either on a psychodynamic or a somatic level are not warranted. In evaluating each patient, one must determine to what extent the treatment approach should be psychotherapeutic, somatic or a combination of both. Furthermore, in different phases of the treatment, different therapeutic approaches may be necessary and a flexible adaptation of technique to the patient's condition is of paramount importance.

In some cases, it was apparent that the patient refused a certain type of treatment or discontinued all treatment when it would have benefited him to accept and continue. There were also instances of patients whose absolute or relative failure to cooperate was realistically motivated and they sought treatment elsewhere or were able to function reasonably well without further help. Another group was characterized by premature discharge from treatment on the basis of superficial gains, oscillations in the intensity of the symptomatology or a shift of symptoms—only to discover no significant change had been effected. A problematical group was the one in which a stalemate was reached in treatment. The patient had become able to function with less discomfort than before but had made no significant progress toward adequate functioning. This situation often continued for years because neither the therapist nor the patient had dared to request a termination or an objective evaluation of progress, such as that suggested by Oberndorf after 300 hours(5). Termination of treatment most often came about, under such circumstances, through economic fatigue on the part of the patient or emotional fatigue on

the part of the psychiatrist. Some of these patients would have benefited from another type of technique or adjuvant treatment. Some would have been able to function reasonably well if they had received a weekly or monthly "ego-transfusion," a situation in which the therapeutic session is roughly analogous to the periodic blood transfusion that sustains certain chronically anemic patients. Precedent for sustaining a patient in this manner is firmly established in medical practice. To do so is both an obligation and a triumph. Specialists in other fields of medicine focus on patients' functioning relatively free of symptoms and rarely speak of "curing." They do not repudiate patients who fail to respond to a given program of treatment; they question the program, not the patient.

A small minority of the patients in our series were apparently inaccessible to all forms of appropriate treatment and pursued a downhill course.

There were a number of patients who had a good or fair outcome, following the application of various types of treatment. Such effectual treatment ranged from that which might be regarded as minimal, in terms of duration and intensity, to a protracted period of intensive treatment. However, the gains appeared to be solidly established when these patients were seen in the follow-up interviews.

Our survey of the outcome of illness leads us to conclude that there is no formula for recommending a specific treatment program that will insure a favorable outcome. Rather, the treatment must be tailored to the individual needs of the patient at a given time, with emphasis on frequent evaluation of his current status and on flexibility in selecting means to expedite his progress. Intensive study of one or two patients who have this type of illness can lead to a ready explanation of the origin of the illness and the outcome of treatment. Certain isolated aspects of the environmental vicissitudes and certain reactive attitudes of the patient can be focussed upon and the illness attributed to these. Such factors can be formulated in any of several frames of reference and the cause of the illness may be stated as obvious. Unfortunately, many of these dynamic formulations do little more

than paraphrase a descriptive appraisal of the patient's personality development and his present illness. The outcome of the patient's illness and treatment is sometimes declared to be closely related to the patient's "accepting" the therapist's formulation. Good outcome is correlated with acceptance and fair or poor outcome, with half-hearted acceptance or refusal and denial.

This study undertakes the investigation of a larger number of patients and the variety of their symptoms, the variable prominence and oscillations of symptoms and a 5-20 year review of the health and functioning of these patients. The results emphasize the necessity for appraisal of the illness of each patient and the formulation of an effectual treatment program. The medical task precludes the intrusion of universal formulas and ritualized therapeutic programs.

SUMMARY

1. This is a 5-20 year follow-up report of the course and outcome of 109 patients with pseudoneurotic schizophrenia, 60% seen initially at Psychiatric Institute and 40% in clinics or private practice.

2. About two-fifths of these patients had had previous episodes of mental illness (inpatients : 42%; ambulatory patients : 31%).

3. There appeared to be a high incidence of a life-long history of illness, though age at onset is difficult to determine. There was a striking concentration of patients in the third (50%) and fourth (25%) decades at the time of beginning treatment.

4. There was a significant incidence of subsequent hospitalization following initial contact : approximately 40% of the entire group was hospitalized 1-9 times (11% of Group 1 and 56% of Group 2).

5. Ten percent of the patients attempted suicide but only 2 patients died by suicide. There were no other deaths in this series.

6. Approximately 20% of the patients developed overt schizophrenic symptomatology at some time during the follow-up period, but half of these (10%) had a remission. Thus 10% who originally had the pseudoneurotic form of schizophrenia developed chronic forms of schizophrenia with the typical catatonic, paranoid and occasionally

hebephrenic symptomatology.

7. At the time of the follow-up study, about one-third of all the patients were found to have a good, fair and poor outcome, respectively. In Group 1, 44% of the patients had a good outcome and another 40% had a fair outcome. In Group 2, one-fifth of the patients were rated as having a good outcome and 40%, a fair outcome.

8. Efforts were made to correlate outcome with various factors, ranging from family history of mental illness, through environmental vicissitudes, reactivity to stimuli, precipitating factors leading to disability, to type of treatment. There was evidence of some correlation with precipitating factor and type of treatment.

9. Forthcoming reports on the development of pseudoneurotic schizophrenia and different approaches to treatment are mentioned and the need for further, more extensive studies of this syndrome is noted.

FAMILY CARE AFTER A THOUSAND YEARS—A CRISIS IN THE TRADITION OF ST. DYMPHNA¹

MATTHEW P. DUMONT, M.D., AND C. KNIGHT ALDRICH, M.D.²

HISTORICAL PERSPECTIVES

The legendary origin of the world's oldest colony for the family care of mental patients concerns the beautiful Irish princess Dymphna who lived in 700 A.D. In an attempt to escape the incestuous advances of her royal father, she fled to Belgium with her confessor. Her father overtook her in Geel, a little Flemish community not far from Antwerp, and summarily decapitated her.

Unaccustomed to a madness of such majestic proportions, the people of Geel preserved Dymphna's body as something of a curiosity, which began to attract visitors from neighboring villages. Gradually the remains of the innocent victim of her father's insanity became invested with magical significance for the mentally ill, and during the next hundred years visits of the curious were replaced by pilgrimages of possessed patients. Dymphna had become a saint.

A church and a series of annexes for housing pilgrims were built. In the healing ritual, the priest first hung a clay amulet engraved with some letters of Dymphna's name about the neck of the patient. The patient then crept on his hands and knees under the reliquary containing the bones of the martyred princess, and was exorcised of the devil causing his insanity. The effectiveness of this regimen is attested by records that go back to the 13th century which often show, next to the names of the pilgrims, the words: "and the evil spirit departed." Although the 13th century psychiatric classification used the moral terms "possessed" and "innocent," the word over the annex to the church of St. Dymphna was "zieckenkamer," which means "sick-room." This is probably the first instance since clas-

sical times that the word "sick" was used in reference to mental abnormalities.

By 1250, the date of the earliest extant record, the tradition of family care had taken firm root in Geel. Presumably the tradition had arisen as the story of the curative powers of St. Dymphna attracted so many pilgrims that the annex could not accommodate them and the Geelose responded to their need of housing by taking the pilgrims into their homes. The official care of the patients continued to be the responsibility of the church, and nursing care was administered by nuns until the 19th century when, under the influence of Napoleon's bureaucratic policy and anticlericalism, the control of the colony was transferred to the French Imperial government. After the boundaries of Belgium were re-established by the Congress of Vienna, the colony was maintained by the municipal government until 1852, when it was placed under the Department of Justice of the Belgian government. It has since been known as the "rijkskolonie" or colony of the state.

In 1821 Esquirol visited Geel and spoke encouragingly of family care but insisted that the central hospital facilities were entirely inadequate. As a result new buildings which have a capacity for 300 patients were constructed on the present site. Between 1860 and 1940 the number of patients in family care grew from 800 to 3700. Since the war, however, new admissions have been discouraged by the authorities in charge of state hospitals, and the patients have steadily declined to 2400. The decline is continuing and, unless present administrative policies change, the future of family care at Geel is precarious, and the colony presumably will be closed in several years. While it still is viable, however, it deserves a careful appraisal. What is the meaning of its decline in a period of increasing enthusiasm for family care as one of a group of promising transitional methods of convalescent treatment? What medical, social,

¹ Read at the 117th annual meeting of The American Psychiatric Association, Chicago, Ill., May 8-12, 1961.

economic or political facets of the Geel story are applicable to family care in the United States?

GEEL TODAY

Geel is a predominantly agricultural community of 20,000 located about 40 minutes from Antwerp by train or auto. The majority of inhabitants live on small farms which yield only enough to satisfy the basic needs of the family. The atmosphere in the town is conditioned by many years of exposure to mental patients. The patients, comprising a tenth of the population, are not treated as a separate class. I have seen coffee served in a cafe with as much deference to actively hallucinating psychotics as to anyone else. There are two movie theaters in the town and on a Sunday evening there are as many patients as townspeople in them. I never saw any revulsion or fear displayed towards patients, although many of them act in a bizarre fashion. About a half dozen incidents of violence have occurred in the past 25 years, two of which resulted in fatalities. Although these were no secret to the populace there was no outcry for more controls. An average of 2 patients a year are involved in automobile accidents, representing, according to police files, a somewhat better record than that of the townspeople. There are about 3 suicides a year among the patients, a rate proportional to that of the other state mental institutions in Belgium.

The standards for selection of foster families are extremely flexible despite an impressive list of criteria in the book of regulations. In practice no more than a room with minimum dimensions and a window for each patient is required. Plumbing is a rare luxury although electricity and bottled gas are now found throughout. A peasant's house often has a thatched roof and a floor of brick and dirt. The main living and dining room, customarily the only heated room in the house, opens on to the bedrooms, an equivalent of a kitchen, and the cowbarn. Privacy has little meaning to the Flemish peasant; doors are rarely locked or knocked at. Often the only decorations are religious icons, usually including a statue or picture of St. Dymphna.

Before the current constricting regula-

tions were imposed upon it, the colony had about 300 admissions a year and between 150 and 200 discharges. In 1960 there were 2100 patients in family care and another 300 in the hospital. In 1959, 141 patients were discharged, 82 by death of which 78 were natural and 4 accidental; 15 were transferred to other institutions presumably because of inability to adapt to family care. Of the remainder, none was discharged as cured, 33 were considered "ameliorated" and 10 "unchanged."

Although the majority of patients are from Belgium and Holland, many are from other parts of Europe and a few from Algiers, United States, New Zealand, and other remote areas. Most of the patients have been in institutions once or more and have been transferred or admitted to Geel at the instigation of an interested physician or family member who has heard of the colony. The majority, who are enjoying the degree of freedom and activity that Geel offers, otherwise would be in the chronic wards of custodial hospitals.

Approximately a third of the patients are women. Most are middle-aged, and some have been there for more than 50 years. There are about 150 minors, some as young as 5 years. Only 6% are supported by their families, at a cost varying with their ability to pay and averaging between \$50 and \$100 a month. For a paying patient, the foster home may receive \$2.00 a day or more. The remaining patients are indigents whose expenses are covered entirely by the state. The amount of money allotted to a foster family for the upkeep of a patient (between 30¢ and \$1.20 a day) depends on the patient's ability to contribute to the comfort or income of the family by working in the fields, in the family business, or in the home. Most families have a maximum of 2 patients permitted by the colony.

When there were new admissions, diagnoses were made after a brief interview by the social worker or staff member or as the patient was seen on rounds during a 5-day initial hospitalization. Fifty-five percent of the patients in 1959 were diagnosed as mentally deficient, 29% schizophrenic, 4% psychopathic personality, 2% manic-depressive and another 2% general parietic. The remaining categories included paranoia, arterioscle-

rotic dementia, epilepsy and involutional psychosis.

The current director, Dr. Hadelin Rademaekers, believes that maximum benefit can be obtained from family care when the patient is completely integrated within the foster family and when their cares and diversions are felt as his own. Dr. Rademaekers is convinced that cases formerly considered hopeless have shown definite improvement on a regimen of family care alone. He is due for retirement in 1962, and three of the other four doctors are in their late fifties. Although Geel is not a rehabilitation center in the modern sense of the word, the physicians on Dr. Rademaekers' staff recognize that for many patients the life in the colony is more pleasant than in a closed institution.

Each of three staff psychiatrists is responsible for a geographical section of Geel containing about 600 patients. The fourth has a smaller section and is also in charge of the approximately 300 patients within the hospital. Each physician is expected to see all his patients at least once a month, and his visits, rarely lasting more than 5 minutes, occupy most of his official time.

Tranquilizers are freely prescribed, and their use often must be left to the discretion of the foster parent. Electroconvulsive therapy is rarely given and there is no time or resources for psychotherapy, group therapy or occupational therapy beyond the equivalents offered in the foster homes. Since patients who have been drinking heavily or who have been destructive or uncooperative are threatened with a return to the hospital, hospitalization is looked upon by most patients as a punishment. This attitude, along with the overcrowding and the locked doors, makes it difficult to give the central hospital a therapeutic atmosphere.

Placements are flexible and made primarily by trial and error. If a patient is evidently making a poor adaptation despite tranquilization, he is simply placed in another family. There have always been more foster homes than patients to fill them so that placements can be repeatedly changed until patient and family are satisfactorily matched. It is possible for a patient to be moved 20 or 30 times before he finally finds a situation appropriate to his needs. Once

this home is found the patient may remain for 20 or more years. On the other hand it is not rare that a patient who has been with a family for many years abruptly falls out of step with it or becomes agitated, and a new placement must be found. Flexibility of foster placements is part of the tradition so that families rarely feel any compunctions about returning a patient. Some patients, however, have been with families for so long that they have become virtually family members, and may be passed on to the children of the families which had originally accepted them. There are therefore a good many adults in Geel who have lived all their lives with the same patient.

A SURVEY OF FOSTER FAMILIES

I (M.D.) went to Geel for two months in the summer of 1960 knowing that the colony was declining and believing that its decline was due to changing cultural patterns and the consequent inability of the colony to find families who would accept patients in foster care. In an effort to get more specific reasons for the presumed decline in availability of foster homes, I had planned a comparative study of families who had dropped out of the program and families who were still participating. To my surprise, I found that there has been no over-all decrease in interested families and I could find only 47 families who were once in the program but had dropped out. I interviewed these families and a random sample of 46 families who have continued to accept patients. The interview data are recorded in Table 1.

The family groups are similar on both sides, although families who have continued appeared more closely knit, as indicated by the higher percentage of continuing families with 3 generations in the home. Relatively more farmers and white collar workers appear in the continuing families, while there are more professionals, entrepreneurs and pensioners in the drop-out group. The higher incidence of pensioners is due to the greater number of older people in this group.

As reasons for originally accepting patients, more of the continuing families than the drop-outs gave such answers as: "It is the custom here," "It is the thing to do in

TABLE 1

	FAMILIES WHICH HAVE CONTINUED TO ACCEPT PATIENTS	FAMILIES WHICH ARE NO LONGER ACCEPTING PATIENTS
Mean number of family members	4.2	4.1
Median number of family members	2	3-4
% of families with 3 generations in the home	13.1%	8.5%
% of families with 2 generations	60.8%	68.1%
% of families with 1 generation	26.1%	23.4%
% of rural houses	36.9%	34.8%
% of urban houses	28.3%	34.8%
% of suburban houses	34.8%	30.4%
Occupations of chief wage earners :		
Laborers	34.8%	37.7%
Farmers	28.3%	13.3%
Entrepreneurs	13.1%	17.7%
White collar workers	10.8%	4.4%
Pensioners	8.7%	15.5%
Professionals	4.3%	11.1%
Stated reasons for having accepted patients originally :		
Custom	34.3%	20.0%
Money	21.4%	24.0%
To help with work	20.0%	36.0%
Patients inherited from parents	11.4%	12.0%
Compassion	4.2%	4.0%
Desire for companionship	4.2%	2.0%
Wanted children	4.2%	0
Requested by staff members	0	4.0%
Stated reasons for having dropped out of the program :		
Too old		24.0%
Too much trouble		22.0%
Not enough room		20.0%
Does not pay enough		12.0%
Fear of incidents		10.0%
No present need for help		4.0%
No present need for money		4.0%
Bad for business		2.0%
All family members work		2.0%
Parents of both husband and wife of this family had patients in their homes	78.3%	56.5%
Only parents of wife had patients	10.8%	10.8%
Only parents of husband had patients	6.5%	15.2%
Neither set of parents had patients	4.3%	17.4%
Mean of total number of patients nursed by each family	4.2	3.9
Median of total number of patients	1	1
% of patients in classes 1, 2 and 3	44.4%	45.1%
% of patients in classes 4, 5 and P	55.6%	54.9%
% of current (or last) patients who have had to return to the hospital more than twice during their stay in the home	12.6%	26.5%
10% of families with patients would not take another patient when the present had left		
Another 9% was undecided. The remainder would con- tinue with other patients		
All families questioned were satisfied with the super- vision of the colony		

Geel." Drop out families more often responded in terms of money or work. Their most frequently stated reasons were age, lack of room, and "too much trouble." In twice as many drop-out families as continuing families the last patient required hospitalization 3 or more times during his stay in the home, suggesting that management problems played a part in discontinuance. The significance of tradition is suggested by the finding that more parents of continuing families than parents of drop-out families had patients in their own homes.

In summary, a family tradition of patient care, rural location, farm or white collar work of modest income, family solidarity, and tractable patients appear to be factors encouraging families to continue to accept patients. More than 80% of the families now caring for patients stated that they would accept another if the current patient were to die or to leave. Apparently, despite a steadily rising standard of living, the inroads of an industrial civilization, and static levels of remuneration, the tradition is not dying out and would persist if allowed to. For other reasons, however, the Geel colony may be doomed. Its ultimate demise would have little effect on the advance of mental rehabilitation and social psychiatry, as family care in Geel is basically a tradition on which psychiatry only lately has been superimposed. The momentum of the tradition has been maintained neither through psychiatry nor through its magical source in St. Dymphna but through the Geelose themselves who know that mental patients are not dangerous. The danger is that a thousand-year-old living monument may be destroyed at the moment the world is recognizing its significance.

DISCUSSION

ROBERT T. HEWITT, M.D. (Boulder, Colo.).—To generations of psychiatrists Geel has served as an image of the humanitarian and compassionate care of mentally ill people. Being the original family care program, it has also served as an inspiration if not a model for family care programs in Europe and North America. Viewed from afar, programs take on a halo effect, while the neighbors view them more realistically and with less reverence.

If we look at Geel, as described by the

authors, through the eyes of western psychiatry certain impressions are gained:

1. The diagnostic procedures seem inadequate for anything but a social differentiation.

2. Treatment seems inadequate. This is custodial care with some partially supervised drug therapy. The hospital seems inadequate in size and is seriously over-crowded and locked.

3. Orientation in the colony does not appear to be directed toward rehabilitation but rather toward resignation to patient disability.

4. Return to hospital is apparently used as a threat in the case of adverse behavior. Hospitalization is thought of by patients as punishment rather than as therapeutic.

We do not know what the reasons are for the "steady decline" reported in resident patients from 3700 in 1940 to 2400 at present. The strangling effect of the ruling of 1958 (Dr. Rademaekers must take personal responsibility for all admissions) will probably, if not altered, result in the closing of the colony. However, it still seems that the colony was in a decline before that. Also before the constricting regulations were imposed, the author reports that there were about 300 admissions and between 150 and 200 discharges per year. According to these data, the colony should have been accumulating patients but actually the resident patient load was falling.

Has the gradual decline in patients been a result of falling off in referrals? Has official policy prior to 1958 forced a decline? Is it possible that Geel, like some of our programs, rested on its laurels and stood still while in the rest of the world care, treatment, and rehabilitation of the mentally ill have moved forward?

In many countries at the present time family care is looked upon as one link in the chain of care, treatment, and rehabilitation, as contrasted with Geel where it is apparently looked upon as appropriate for all patients except those needing closed hospital treatment. Other countries using family care see it as a valuable adjunct to treatment. These patients usually have no home of their own to go to or for some reason a home placement is inappropriate for the family or the individual patient. In some cases it resolves into a more or less permanent placement and in others a temporary placement as the patient proceeds to more independent living.

At Bielen, Holland, there is a family program, where patients are admitted to a central hospital of 100 beds and are studied and a diagnosis made and a treatment and rehabili-

tation program planned. Patients are placed in families if this is appropriate. Rehabilitation is the goal. About 300 patients are carried in family care in homes within walking distance of the hospital. They go to the hospital daily where they engage in industrial pursuits, occupational therapy, or maintenance work. This is thought to be analogous to living at home and working at the factory or office.

The first family care program in the United States was in Massachusetts in 1885. Development of family care in public mental hospitals in the U. S. has been slow. In 1950 there were approximately 4900 patients in family care and in 1960 this increased to 9600 in public mental hospitals. The Veterans Administration program has developed more rapidly. Beginning in 1950 it is up to 3000 or 4000 placements at the present time. The program in family care has really been activated in only about 10 states. More and more consideration is being given to the relationship of family care to day hospitals, halfway houses, and rehabilitation workshops where work supervision is available for family care patients. When psychiatric treatment is required, they are returned to the hospital.

Two studies carried on in Veteran Administration hospitals throw some light on outcomes in family placement and on predictability and adjustment of the patient in family care :

Ullman and Beckman, Palo Alto V. A. Hospital, in the *Journal of Social Work*, April 1959, studied patient adjustment not only from the point of view of the goal of remaining out of the hospital but also the goal of reaching independent living outside of family care. They found that in predicting outcome of adjustment

of patients the three main factors were : amount of hospitalization ; type of ward ; and number of admissions.

Patients with the longest hospital residence were more likely to continue in the family care home and not go on to independent living than those with shorter hospital residence. Patients from poor wards were more likely to continue in the family care home than to proceed to independent living. Patients with the greatest number of admissions in the past were more likely to remain in the family care home than to go on to independent living. They also found that some patients remained in the family care home for such a short time that it could not be considered to be a rehabilitative placement.

Lyle and Train, American Lake Hospital, in *Social Work*, January 1961, found that the important factors leading to good adjustment in a family care home were : 1. Age ; patients over 40, particularly those from 60 to 69 made the best adjustment ; 2. Patients hospitalized more than 10 years made a better adjustment than those hospitalized for a shorter period ; 3. Patients showing a capacity to relate to someone adjusted better ; 4. Patients having shown predictable behavior of a non-erratic nature were more likely to make a better adjustment ; 5. Patients showing lack of initiative and drive toward change.

These investigators found that patients changed in the foster home whether they adjusted to it or not. Patients became more alert and active ; more interested in their surroundings ; posture, expression, and bearing changed markedly. It was felt that these were due to the stimulating effect of foster care.

AUDITORY STUDIES IN SCHIZOPHRENIA¹

ARNOLD M. LUDWIG, M.D., BENJAMIN S. WOOD, JR., M.D.,
AND MARION P. DOWNS, M.A.²

This pilot study was initiated for the purpose of investigating the auditory behavior of schizophrenics. The investigators sought to determine whether the hearing acuity of the schizophrenic differed in any way from normal and whether the presence of auditory hallucinations might be correlated with any such differences. In addition, a preliminary attempt was made, through the use of several audiological procedures, to assess the schizophrenic's auditory perceptual apparatus.

Prior work in this field has been scanty and inconclusive. Travis(1), in 1924, described a rise in auditory threshold in dementia praecox patients while crystal gazing compared to psychoneurotics, whereas Bartlett(2) somewhat later found no appreciable difference in auditory acuity between dementia praecox patients and normals. More recently, Camp(3) tested the ability of schizophrenics to distinguish a signal word from background noise and found that paranoid schizophrenics showed a greater impairment in test performance than most of the other groups tested. Studies of a different nature, such as the use of the delayed auditory feedback test, have been employed by Goldfarb and Braunstein(4) on schizophrenic children, while Bergman and Escalona(5) have made some interesting observations on psychotic children who displayed unusual sensitivities to stimuli of various sensory modalities.

METHOD

Sixty-six schizophrenic subjects were selected at random from the inpatient population of Colorado Psychopathic Hospital over a 10-month period and tested very soon after admission. Twelve subjects were eliminated for a variety of reasons, including questionable diagnosis, failure to cooperate, questionable or diagnosed ear

pathology. The remaining 54 subjects were then classified into one of the 3 following groups: (a) those who showed auditory hallucinations at the time of admission; (b) those who had auditory hallucinations in the past only; and (c) those who gave no evidence of ever having had auditory hallucinations.

A control group of 54 subjects was selected at random from all categories of hospital personnel. The characteristics of the control group and the 3 schizophrenic groups, relating to sex and age distribution, as well as the distribution of the diagnostic subgroups in the case of schizophrenics, are summarized in Table 1.

Five audiometric tests were used: 1. The pure tone threshold (PT); 2. The speech reception threshold (SRT); 3. The tone decay test (TDT); 4. The audio-delay or delayed auditory feedback test (AD); and 5. The signal-to-noise ratio (S/N).

The procedure and experimental conditions were approximately constant for all subjects, testing being carried out in a double-walled, sound-isolated room by the same experimenter. A Beltone 15 B Audiometer was used to test pure tone hearing according to AMA accepted audiometric procedure(6). The measure of pure tone threshold was taken as the average of the threshold readings at frequencies of 500, 1000 and 2000 cycles per second, recorded for each ear separately. The audiometric calibration was checked weekly with an Allison audiometer-calibration unit.

Speech reception threshold was measured as the lowest sound intensity at which subjects could distinguish spoken words with 50% accuracy in each ear. A Grason-Stadler Speech Audiometer was used in conjunction with C.I.D. W-2 recordings of phonetically-balanced Spondee words, according to the standardized technique for measuring this threshold(7).

The tone decay test was carried out with the procedure described by Carhart(8). In this test, a threshold tone is presented to

¹ Read at the 117th annual meeting of The American Psychiatric Association, Chicago, Ill., May 8-12, 1961.

² Dept. of Psychiatry, University of Colorado Medical Center, Denver, Colo.

TABLE 1: SAMPLE CHARACTERISTICS

		Sex		Age	Mean	Type Schizophrenic Reaction								
Groups	No.	M	F	Range	Age									
Controls	54	15	39	21-56	32.0	paranoid	undifferentiated	schizo-affective	catatonic	hebephrenic	simple	mixed	unknown	childhood
Present Hallucinations	22	9	13	16-43	29.5	15	2	2	1	1	1	0	0	0
Past Hallucinations	9	4	5	15-56	37.6	5	1	1	0	0	0	1	1	0
No Hallucinations	23	12	11	14-49	28.6	16	2	1	0	0	2	1	0	1

the subject for 1 minute, the subject designating when he no longer hears the sound. If the tone appears to fade before the minute is up, it is raised by 5 db increments until the subject can "hold" the tone for a full minute. Test performance was recorded as being either "normal" or "abnormal." Normal was defined as the ability to "hold" a tone for a full minute either at threshold or 5 db above threshold, while an abnormal response was recorded whenever the tone had to be raised more than 5 db above threshold in order for the subject to hear the tone for the required minute. The frequencies 500, 2000 and 4000 cps were selected for the study. Since the 4000 cps frequency has been found in other studies (9) to be an unreliable indicator of ear pathology, the present investigators distinguished between subjects showing abnormalities in any of the 3 frequencies and those showing abnormalities in either or both of the 2 lower frequencies.

In the delayed auditory feedback test the subjects were given emotionally neutral fourth-grade reading material and instructed to read a short passage through twice, the first time reading it through as well as possible without auditory feedback, the second time with their voices returned through earphones at a 70 db sensation level with a 0.2 second delay. The difference in seconds between these two readings was

used as the measure of the effect of the auditory feedback on reading time.

The signal-to-noise ratio has been considered a means of measuring the subject's acoustic ability to distinguish figure from ground (3). In this test standardized Spondee words, employed as a signal, were played at a constant volume of 30 db above each subject's speech threshold, while speech noise was gradually introduced at 2 db increments until the subject could no longer repeat the words. The point at which the subject could no longer distinguish between the signal words and the speech noise was used as the measure.

RESULTS

The results of each test for each group of subjects are tabulated in Table 2. Inspection of the values obtained for the PT and SRT reveals fairly close agreement among all groups. This impression was confirmed on statistical analysis: no significant mean differences were demonstrated among any of the 3 schizophrenic groups or between the total schizophrenics and the controls. These results are, moreover, generally comparable to the mean values for the PT and SRT obtained in the Wisconsin Survey of 1954 (10).

Audio-delay responses, however, revealed rather striking findings. A plot of the frequency distribution of the individual values

TABLE II: TABULATION OF RESULTS

	PT (db)		SRT (db)		TDT (% abnormal)		AD	S/N
	right	left	right	left	500-2000- 4000cps	500- 2000cps		
AH	21 -8.1	20 -8.6	21 +2.7	20 +2.3	19 74%	19 58%	12 +44.9	16 +8.1
NH	22 -6.1	20 -7.0	23 +0.5	20 +0.6	23 74%	23 48%	13 +42.0	20 +8.1

of the total schizophrenics compared to the control group demonstrated a bimodality of the schizophrenic responses with the median of the control responses falling in the valley between the two schizophrenic peaks (see Fig. 1). On subjecting these distributions

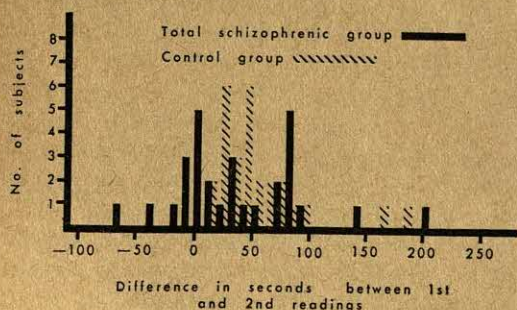

Fig. 1: AUDIO-DELAY DISTRIBUTIONS

to read the same passage. Of the total schizophrenic group, 38% seemed relatively unaffected in their reading time under conditions of delayed feedback, and what seems more remarkable, 55% of this same group actually read the test passage in a shorter time than it took them to read the same passage with no auditory interference. In contrast, all of the control subjects were affected by the audio-delay to some extent, this being demonstrated by the relative slowing in their reading rates.

Significant findings were found also in the TDT test. When abnormal responses at any of the 3 frequencies were analyzed, no significant differences between schizophrenics and controls were found. However, when the unreliable 4000 cps frequency was eliminated, there were 55% abnormal schizophrenic and 10% abnormal control responses on either of the remaining two frequencies, and chi square analysis for these latter values indicated extreme significance with p less than .001. Additional analysis, comparing TDT to AD performance on a scattergraph, failed to reveal any suggestive correlations.

to a Kolmogorov-Smirnov Two Sample Test analysis, it was found that the two distributions differed significantly at a p value of less than .01.

It thus appears that the schizophrenic patients reacted to delayed auditory feedback in essentially 2 different ways: they took either longer or less time than controls

Another interesting finding in the TDT was the observation that 39% of the schizophrenics could not detect the cessation of sound 10 seconds or more after its withdrawal, some subjects even claiming to hear the sound up to several minutes later. Since none of the control group displayed this behavior, the occurrence of this finding in the schizophrenic group was found to be of considerable significance (chi square equals 10.2; p less than .005). However, additional analysis revealed that this particular type of response bore no significant relationship to the previous type of TDT abnormality mentioned.

The results of the signal-to-noise ratio test revealed the most statistically significant differences between schizophrenics and controls. The obvious differences shown in Table 2 are graphically illustrated in Fig. 2,

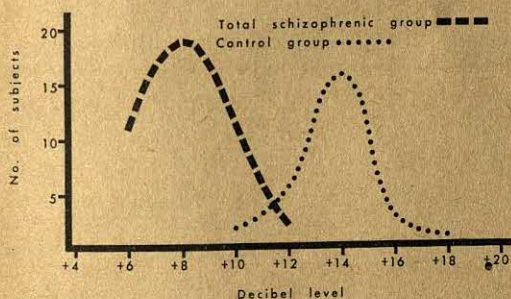

Fig. 2. SIGNAL-TO-NOISE RATIOS

where it can be seen that there is hardly any overlap in the distribution curves of the schizophrenic and control group responses. Comparison of these two sets of responses revealed an F value of 80.1, indicating that the probability of such an occurrence due to chance was less than .001.

It should be mentioned that in none of the 5 test categories could any significant differences be discovered in test performance among the 3 schizophrenic groups. In addition, an attempt to correlate the occurrence of two or more significantly abnormal test responses in the same subjects likewise proved fruitless. Scattergraphs for the age distributions for the 5 tests revealed relative homogeneity with approximately the same proportions of subjects showing abnormal responses in each decade. Also, the patients' final disposition appeared to

have no significant relationship to test results, those requiring long term hospital commitment being as evenly distributed as those who were released. Analysis of the diagnostic subgroupings of the schizophrenic patients was not undertaken as it was felt that the predominance of the paranoid group and the small numbers in the other groups would not lend themselves to valid statistical treatment and interpretation.

With regard to concurrent treatment of the hospitalized subjects, 33 of the 54 schizophrenics (61%) were found to be on some type of medication at the time of testing, 31 of whom received a phenothiazine type drug. A detailed statistical evaluation revealed that medication effects played no role in test performance.

In view of the highly significant differences between the schizophrenic responses and those of the controls to both the TDT and AD, a retrospective attempt was made to determine if any correlations could be found between test performance and the presence in schizophrenics of any common personality traits or symptom complexes. It was believed that the discovery of any common denominators in this respect might provide better clues as to the possible theoretical meaning of the observed differences, or at least point the way toward more fruitful exploration of any such factors through more specifically designed future experiments. The charts of the schizophrenics were reviewed independently by two of the authors, and each individual subject was evaluated with respect to certain characteristics, such as degree of withdrawal, aggressiveness, negativism, anxiety, affect disturbance, thought disorder and overt length of the disease process. Within the serious limitations of chart analysis, varying degrees of inter-rater reliability were obtained on the two separate ratings; however, none of these variables was found to have any significant relationship to test performance.

DISCUSSION

Despite the limitations inherent in the nature of any pilot study, these investigations have pointed up some interesting and significant features in the auditory performance of schizophrenics.

The results of the PT and SRT tests appear to indicate that the actual hearing acuity of hospitalized schizophrenic patients is approximately equal to that of the population at large. In addition, no quantitative differences in auditory acuity could be demonstrated between groups of hallucinating and non-hallucinating schizophrenics. The fact that schizophrenics could perform normally on these tests suggests that the subjects could function adequately under test conditions.

The behavior of the schizophrenics differed significantly from the controls in each of the 3 remaining tasks. In attempting to understand these differences, it should be recognized that the TDT, AD and S/N ratio tests all differed considerably from the others, both with respect to the nature of the test and the demands made by the test on the subjects. In all of these tests, the subjects were required to direct more attention to a complicated task for a longer period of time. Moreover, in the case of the AD and S/N tests, subjects were required to assimilate and integrate a barrage of conflicting auditory stimuli.

Despite the somewhat different nature of the task in these tests, an explanation of the real meaning and significance of these findings is not readily available. However, one might speculate on the theoretical possibility of an autonomic inhibitory action on the excitability of the hair cells to account for these results. Recent anatomical and neurophysiological work on cats lends support to this tentative hypothesis. Rasmussen(11) has traced efferent cochlear fibers in the cat from the contralateral olivary nucleus to supposedly the hair cells themselves, and there is suggestive evidence that a similar "olivo-cochlear bundle" is present in man. Galambos(12-14) has extensively studied the functions of this bundle and concluded that these fibers, when functioning, suppressed the expected inflow of auditory nerve activity to normal acoustic stimuli. By measuring the micropotentials of the auditory nerve in the cat, he found that the amplitude of the nerve's response to a click stimulus was significantly reduced if a barrage of impulses simultaneously arrived at the cochlea via the olivo-cochlear bundle.

It might be further postulated that this

pathway may be selectively utilized in some schizophrenics as a means of avoiding disturbing auditory stimuli. Activation of such a pathway possibly could represent a peripheral neurophysiological correlate of the defense mechanism of psychic denial. As Linn(15) holds, interference with perception facilitates denial and, conversely, the need to deny can result in functional disturbances of perception.

The combined use of denial and neural inhibition might explain some aspects of the schizophrenic's abnormal behavior on the TDT, AD and S/N tests, although it is not clear why some schizophrenics should be affected and others not. Furthermore, it is difficult to account for the fact that abnormal test performance on one test could not be correlated with abnormal performance on any other test or with clinical personality traits of the subjects. It is obvious that much more work is necessary, both at the neurophysiological and clinical levels, to elucidate the meaning of these results.

There are several limitations of this pilot study which should be considered. Subjects might have been tested several times during their hospitalization to note whether changes in test performance could be correlated with changes in their clinical status. Also, other diagnostic categories of hospitalized patients could have been included to determine the specificity of these findings in schizophrenia. A clinical evaluation of the subject's state of anxiety prior to and during test performance, as well as his utilization of the defense mechanism of denial, would be useful information to have, provided adequate measures of these variables can be devised. It is hoped that some of these difficulties can be remedied in future investigation.

CONCLUSIONS

1. The present findings indicate no significant difference in performance on the PT or SRT tests, either between schizophrenics in general and controls, or between hallucinating and non-hallucinating schizophrenics.

2. In response to conditions of delayed auditory feedback, schizophrenics as a group showed significantly different responses from controls. These responses in-

licated that the schizophrenics tended to be either more or less greatly affected than controls in their reading times.

3. Two types of abnormal responses to the TDT were found. First, schizophrenics in general showed significantly more rapid adaptation to given sound frequencies than controls. Since none of the subjects in this study revealed any evidence of gross hearing abnormality, this phenomenon cannot necessarily be considered as pathognomonic of cochlear or retrocochlear damage as previous studies on normals have indicated (8, 9, 16, 17). Second, the inability to detect withdrawal of the tone was observed in a large number of schizophrenics but not at all in controls, a finding which has not been previously described.

4. Schizophrenics showed significantly more difficulty in distinguishing a signal word from background noise compared with normals.

5. No significant intercorrelations could be demonstrated among the several abnormal test performances. Analysis of personality traits, as well as the use of drugs and necessity for long term hospitalization, did not appear to affect test performance.

SUMMARY

A pilot study was undertaken to evaluate some quantitative and qualitative aspects of schizophrenics' auditory behavior by means of 5 auditory tests. It was found that schizophrenics displayed completely normal auditory acuity on the pure tone and speech reception threshold tests, whereas they displayed significantly more abnormalities than controls on the tone decay, delayed auditory feedback and signal-to-noise ratio tests. There were no significant correlations between abnormal test function and other variables analyzed. The possibility of a peripheral neural inhibition working in conjunction with psychic denial was dis-

cussed as possible mechanisms accounting for these findings.

ACKNOWLEDGEMENT

We would like to thank Drs. Herbert S. Gaskill, John D. Benjamin, Victor H. Hildyard and Donald W. Stilson for their many helpful suggestions.

PSYCHOLOGICAL AND BIOCHEMICAL SYNTHESSES OCCURRING DURING RECOVERY FROM PSYCHOSIS^{1, 2}

SAMUEL BOGOCH, M.D., PETER C. BELVAL, KARL T. DUŠSIK, M.D.,
AND PETER C. CONRAN, M.B.^{3, 4}

The recovery from a psychotic disorder is marked by a transition from a disintegrated, fragmented and chaotic state to one which is more integrated, unified and orderly. These changes imply regrouping and putting together of functions, that is syntheses. The functions, as they are manifest in behavior, may be described in behavioral terms, but the steps taken in the reorganization of these functions in the nervous system, described in psychological terms, have been little studied. Similarly, nothing is known of the biochemical changes which might occur during such recovery. Recent studies in this laboratory (1-5) have been directed towards a better understanding of these phenomena.

With the development of new methods for the study of chemical constituents in the nervous system itself (6) it has been possible to demonstrate quantitative changes in these constituents occurring during recovery from psychosis which suggest preferential chemical syntheses. Evidence that psychological and biochemical changes occur in close temporal relationship in double-blind studies on patients will be presented. The hypothesis here considered is that these

changes, occurring during recovery from psychosis, represent syntheses, and that these are unitary syntheses of nervous system functions which may be open to description and understanding in both psychological and biochemical terms. That some experimental methods as illustrated here are now available for approaching these phenomena is encouraging; but the experimental evidence obtained with these methods must be clearly differentiated from the hypotheses arising therefrom, and the preliminary nature of these investigations recognized.

METHODS AND PATIENTS STUDIED

The neurochemical and clinical double-blind methods employed in these studies are described in detail elsewhere (1, 6). To the 24 cases with psychotic states previously reported in longitudinal studies (1) 33 cases are added in this report; total 57 cases. All have been selected at random for study by both clinical and chemical methods. The age range is from 17 to 61. Schizophrenic, affective, and mixed psychotic disorders are included. Both first and multiple admission cases are represented, as well as patients hospitalized constantly over many years. Twenty-eight of these patients were treated with various pharmacotherapies, 19 with EST, 3 combined EST and pharmacotherapy, and 7 no specific therapy.

TERMINOLOGY

One of the limitations in studying and discussing psychosis (or the psychotic state) lies in the indefiniteness of the descriptive terminology used. For instance, the tendency occurs to associate the psychotic state with particular personality types rather than to deal with it as a particular behavioral state with certain definable characteristics which may occur in all personality types. The current nosology (7) is subjected in its use to so much individual variation and interpretation that distinc-

tive and comparable groups of patients in different geographic sites are difficult to identify and compare in different studies.

In an attempt to avoid semantic disorder and to characterize as accurately and reproducibly as possible the behavioral states, it would appear useful to indicate briefly those elements which are taken in this study to characterize and define the psychotic state (Table 1). These elements are those

TABLE 1
Some Characteristics of the Psychotic State

Symptoms and Signs	
1. Anxiety	Overt signs of extreme anxiety, fear, terror.
2. Rate of processes	Increased in excited or manic states, decreased in retarded or depressed states.
3. "Filtering" or regulation of sensory input	Increased in extreme withdrawal, decreased in manic reactions.
4. Mood	Extremes of hyper-elation and depression.
5. Organizing, focus—and continuity—ability	Disorganization, indecision, memory disturbances, fragmentation of thought.
6. Maintenance of ego boundaries	Failure to distinguish intra- from extrapersonal events, delusions, hallucinations.
7. Integration of intellectual and affective processes	Dissociation, inappropriateness between elements of behavior.
8. Drive for survival and gratification	Extreme isolation from supporting environment, ineffectiveness and inappropriateness of social action, self-destructiveness.

referred to in the ordinary clinical "mental status" appraisal of the patient's progress, and, for the most part, represent psychological functions or concepts in common usage. The elements are stated in a physiological frame of reference such that no element is foreign to the normal state of psychological functioning but simply is represented in psychosis by an extreme over- or under-exaggeration of the mean. This leaves open the assignment of limits to the mean within particular situational and cultural contexts but makes the extreme positions more readily agreed upon and therefore more readily studied. In addition, it permits clarification and specification in the use of such terms as "improved" which, as now employed, may simply mean for example that a hyperactive process of a given patient, perhaps annoying to the ward personnel, has been replaced by hypoactivity (perhaps in itself extreme) without significant change in any of the other features of the psychotic state. The terms "no change," "slight," "moderate" or "marked" improvement are here used to refer to

marked changes toward the mean in none, approximately one-quarter, one-half or all respectively of the eight items listed, unless otherwise specified. With "worsening," this yields a 5-position scale. More adequate quantitative measurement of these changes is unfortunately not yet in use but is being sought.

The terms schizophrenia, manic-depressive, *etc.*, are employed in the classical descriptive usage(7) in terms of personality characteristics observable at the time of examination and observed in the patient's history. These terms are independent of those used in the description of passage to and from the psychotic state since, for example, it is clear in this frame of reference that the schizophrenic patient is not always psychotic, and that recovery from the psychotic episode does not necessarily imply changes in the "style" of personality functioning of the patient which led to the use of the descriptive term schizophrenia. Finally, the limitations of terms such as schizophrenia even when used in the personality descriptive sense are well recognized. In the majority of psychiatric patients the predominance of different groups of defenses and different "styles" of functioning characterize different periods of their lives. For these patients this part of the "diagnosis" may indeed shift. Nevertheless, the terms remain useful in a research protocol when employed to describe the current mode of functioning of the patient. For a minority of patients, in addition, the passage into adolescence, maturity, and senescence sees no essential change in markedly disordered personality structure, and descriptive terms such as schizophrenia remain constant and appropriate. It is these small, clear-cut groups which offer the best opportunity for reproducible study, and it is with these that most of our studies are concerned.

The susceptibility to occurrence and recurrence of the psychotic state is probably a feature which can be separated at least partially from the personality characteristics of a given "classical" descriptive group and may well have more primary relevance to the occurrence of and recovery from the psychotic state as here defined. This factor of susceptibility to psychosis is probably related to abnormal lability in the regulatory

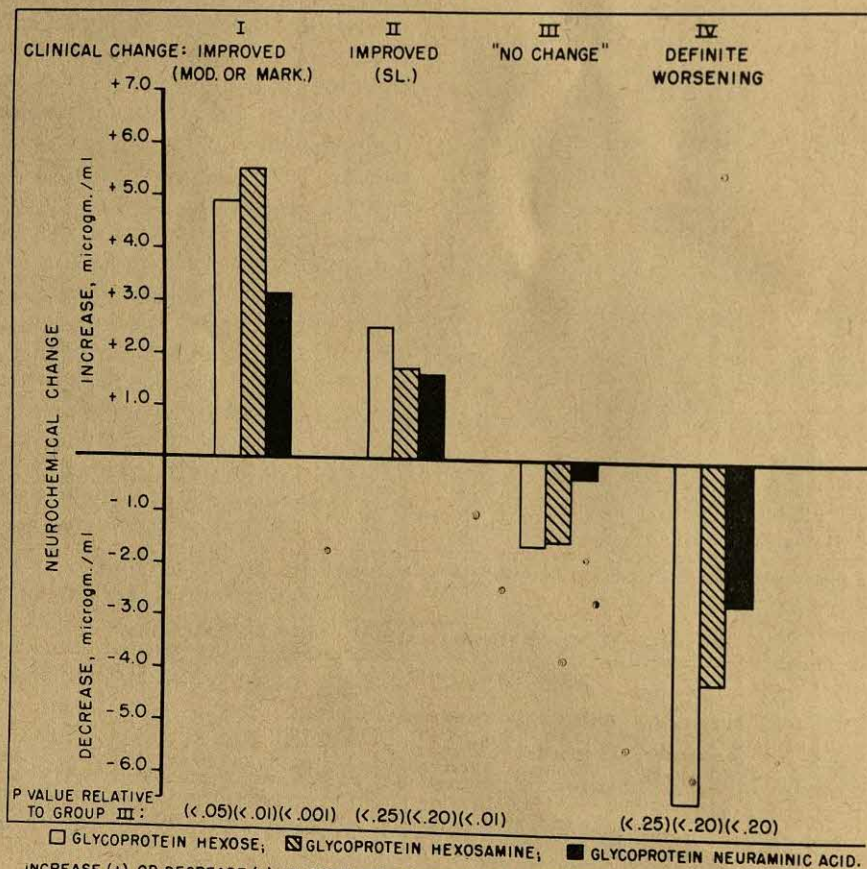

processes for the eight items listed, but cannot be usefully further defined in the present state of knowledge. It is simply noted as one further area, probably of considerable importance, for which our knowledge is meager.

RESULTS

Figure 1 shows the relationship of increase or decrease in absolute amounts of CSF glycoprotein constituents in 65 in-

each of three constituents in the cases of moderate and marked improvement, and for neuraminic acid in the cases of slight improvement. (P values in Table 1 refer to comparison with values in "no change" group.) In cases where no significant clinical change was reported in these double-blind studies, there was a tendency for glycoprotein hexose and hexosamine to be somewhat lowered suggestive of slight worsening in at least some of these patients.

FIGURE 1 *

INCREASE (+) OR DECREASE (-) IN ABSOLUTE AMOUNTS OF GLYCOPROTEIN CONSTITUENTS IN 65 INSTANCES OF IMPROVEMENT, "NO CHANGE," OR WORSENING IN THE CLINICAL STATUS OF 47 SCHIZOPHRENIC PATIENTS DURING ENTRY INTO AND RECOVERY FROM A PSYCHOTIC STATE.

* With a correction for small numbers, three of the p values change as follows: Group IV neuraminic acid $p < .01$; Group II neuraminic acid $p < .005$; Group IV hexosamine $p < .40$.

stances of improvement, worsening and no change in 47 schizophrenic patients examined in longitudinal studies to date (see Tables 2-4, and paper I(1) for remainder of the data; 173 clinical and chemical evaluations on 57 patients).

It is clear from the data in Figure 1 that a significant correlation exists for changes in

Group I (improved) and IV (worsened) differ markedly in concentration of both neuraminic acid and of hexosamine ($p < .001$) and of hexose ($p < .01$). Not shown in Figure 1 is that early samples in cases concluding with moderate or marked improvement demonstrated even higher values of hexose $M = +4.32 (\pm 2.71)$ and of hexosa-

mine $M = +7.72 (\pm 5.63)$ than those present later when neuraminic acid was at its height. This is again suggestive that hexose

and hexosamine may be considered as precursors for the synthesis of neuraminic acid (2).

TABLE 5

Summary of 75 Instances * of Improvement, Worsening and No Change in the First 57 Cases Studied by Combined Double-Blind Clinical and Neurochemical Studies

Presence or Absence of Correlation of Clinical and Neurochemical Data	Number	Total Number
1. Presence of correlation		70
a) Neurochemical changes coincident with clinical improvement	45	
b) Neurochemical changes coincident with clinical worsening	12	
c) No significant changes in either clinical or chemical status	13	
2. Absence of correlation		5
a) Clinical improvement but no coincident neurochemical change	3	
b) Clinical improvement but neurochemical changes indicative of worsening	2	

* The total number of examples of presence or absence of correlation exceeds the total number of cases since in 18 of the cases studied, instances of both clinical improvement and worsening were observed in each case.

DISCUSSION

The changes which occur are referred

nated function. Survival and gratification functions are considered as the total expression of the desire to preserve the organized (live) state as distinct from the more random (dead) state of organization, and are indicated by clinical evidence of the energies devoted to nurture and growth as opposed to those devoted to injury and destruction.

It may be considered that none of these functions can operate at a highly organized level 1. If the level of anxiety is too high; 2. If the rate of processes is so excessive or so degraded that the ability to coordinate discrete functions is impaired; 3. If the normal filtering of sensory input is so decreased that the organizing "matrices" are bombarded by discontinuous and irrelevant

units of information from the outer world or from bodily processes and other thought processes; and 4. If mood is so extreme that, through rate phenomena alone, and possibly through physico-chemical "field-effects" the function of multineuronal matrices is impaired.

At the present time it would appear of interest to view these changes in this way for the purposes of following stages in the recovery process. This formulation represents only an initial frame of reference for future detailed study. The scheme is tentative, preliminary, and requires much testing before any conclusions can be reached as to its usefulness.

Chemical Syntheses. The tendency for enrichment to occur in a particular constituent of these nervous system glycoproteins has been shown to be independent of overall increases of total glycoprotein, and independent of the type of treatment employed (1). Evidence has also been presented that these changes are independent of diet and of the age of the patient (1). These chemical changes appear to correlate with changes in clinical status as shown here and elsewhere (1). That they reflect changes in permeability of membrane barriers, or release of certain constituents from stored sites seems less likely in view of the failure for the concentration of total glycoprotein to correlate with changes in particular constituents; in fact, the total glycoprotein often is decreased at the time that particular carbohydrate constituents are markedly increased (see (1) and cases 477, 527, 529) suggesting preferential synthesis. The investigation of these changes by radioactive biosynthetic studies is now in progress.

Hypotheses Regarding Correlations of Psychological and Neurochemical Events.

It is important to recognize at the outset that there are no known correlations between the psychological events and the neurochemical events here described, except that they occur at the same time in the same person. On the other hand, no chemical changes of this type in the nervous system itself of the patient under study have been previously known whereby correlations with psychological events might even be hypothesized. Since these changes are in nervous system constituents, the

probability that they have primary relevance to nervous system function appears increased.

At this stage of our studies, statements of extensive correlative hypotheses are not indicated. Some clues for further investigation may be noted however. Thus, 1. A change in the type of and occasionally in the total content of glycoprotein present in one compartment of the nervous system itself, the cerebrospinal fluid, occurs with the entry into and recovery from psychosis; 2. This change is often highly selective in terms of the particular carbohydrate moiety which is most involved; 3. The synthesis (or release) of glycoproteins containing greater or lesser amounts of hexose appears to correlate with mood changes; 4. Increased hexosamine appears to be associated with decreased anxiety, a change in the rate of processes, change in focus and continuity ability and changes in the maintenance of ego boundaries (the changes in glycoprotein hexosamine may have some relationship to changes in other amines in the nervous system observed in animals when monoamine oxidase inhibitors are administered and postulated to be related to affective states in humans); 5. Increases in neuraminic acid appear to be more associated with fundamental improvement in organization, integration, and maintenance of ego boundaries. Whether the accumulation of hexoses and hexosamines (precursors) bound to proteins taken together with a failure of accumulation of neuraminic acid (derivative) represent some form of enzymatic block in biosynthesis (2), and whether the correction of this disturbance might be accompanied by clinical improvement remains an intriguing subject for further study.

These are only tentative and highly speculative hypotheses and must be clearly distinguished from the quantitative nature of the data from which these hypotheses arise.

CONCLUSIONS

Quantitative neurochemical changes and the absence of change have been observed in patients in the glycoproteins of one compartment of the nervous system itself, the cerebrospinal fluid, which are temporally related to psychological and behavioral

changes or the absence of change respectively occurring during entry into and recovery from psychotic states. The psychotic state is defined in a manner which permits some quantification of the disturbance in terms of groups of psychological functions involved. The hypothesis is considered that the functional changes in recovery from psychosis may be usefully viewed as syntheses, and that the functional synthetic changes which occur in the nervous system are unitary even though they may be investigated and described in both psychological and biochemical terms.

DISCUSSION

MAX FINK, M.D. (Glen Oaks, N. Y.).—Dr. Bogoch and his co-workers have presented another in their series of studies relating spinal fluid changes to behavioral alterations in a variety of psychotic states treated by drugs, insulin, ECT, and time. In this report they add 33 cases to their original 24 for a total of 57 cases. In these studies they are making a variety of broad generalizations which, if true, would reflect a remarkable insight on their part of basic biochemical mechanisms related to behavior.

It would be inappropriate for me to inquire into the reliability of their biochemical measures, since I am confident that the authors have convinced their biochemical colleagues that the error variance in their methods is much less than the changes on retesting. Further, I trust that the authors have taken the simple precautions of dividing their samples at the bedside into duplicate fractions,

so coded that the biochemist is not aware that he is testing the same samples and that the sample values are sufficiently alike as to warrant our reliance on the biochemical procedures.

I would attend to their general theoretic formulation in the hope that my inquiry may serve to prevent the authors from disappointing us and themselves. In assuming a unitary biochemical basis for schizophrenic illnesses (and implicitly in their other reports for depressive illnesses and chronic brain syndromes) they follow a long line of biochemical investigations in recent years whose first reports created feelings of optimism in our society—feelings that were disappointed time and again.

Their theoretic basis begins with a view of psychosis as a disintegrated, fragmented and chaotic state, and recovery as the transition to a more integrated, unified and orderly one. They then suggest that these syntheses in behavior are accompanied by biochemical syntheses in the nervous system. Thus, they argue for a one to one relation between a biochemical synthesis and a behavioral synthesis.

They further suggest that the basic biochemical processes are reflected in the spinal fluid glycoprotein metabolism, and document their thesis with detailed measurements in the wide range of chronic psychotic subjects. Their data are clear. Those schizophrenic patients who demonstrated a moderate or marked increase in synthesis in behavior showed also significant increases in CSF glycoprotein hexose, hexosamine and neuraminic acid. Finally, the patients who showed either minimal improvement or no change in behavior showed no change in the biochemical measures.

Thus, in a complex biochemical measure, the authors find a unitary reflection of behavioral change. Such findings are indeed exciting, if true. I, for one, have serious doubts that such simple unitary patterns will be substantiated in further testing and can only plead with the authors for a careful statement of their observations. One wonders why, with the original clues available more than 18 months ago, the authors have not taken spinal fluids from a series of schizophrenic patients treated with one treatment modality alone. I am also puzzled by the note that these 33 patients were studied from October 1957 to January 1960, and why they were not available in the 1960 report before the Society. Is it because the biochemical procedures are so complex as to require many hours of analysis? If so, how stable are the tested elements in such fluids over time?

I am also concerned by the failure of the authors to specify such seemingly obvious factors as duration of illness, age and sex of subjects.

Some years ago our laboratory undertook a study of the changes in spinal fluid cholinesterases in psychotic subjects undergoing convulsive therapy. We failed to find the anticipated behavioral-biochemical relationships. We did observe, however, that pretreatment cholinesterase values were related more to age than to diagnosis or state of illness; and that changes in values were positively, though poorly, related to other physiologic indices, but not with improvement. In view of this experience, and the fact that other biochemical-behavioral hypotheses have foundered on such simple variables, I would urge the authors to first assess their data as potential reflections of these more simple relationships.

Finally, I am also troubled by the need of the authors to develop an elegant theory of behavioral change to provide the framework for their biochemical change relationships. Since they have seen fit to use one nosologic schema in their statement of schizophrenia, perhaps they would be willing, for heuristic purposes, to make a comparison of their biochemical changes with the more conventional schemata of improvement, and include such data in a later report. It is apparent that the authors are treading the brink of tautology and there seems a clear need for anchoring their observations in more stable behavioral data.

I find these observations most remarkable. Should this laboratory indicate the reliability of their techniques and their findings, it would then be imperative for other laboratories to substantiate the validity of these tests.

AUTHOR'S REPLY TO DISCUSSANT'S QUESTIONS

The authors wish to thank the discussant

for his comments and reply as follows to his questions:

1. Duplicate determinations, double-blind precautions, error variance and relevance to age are all described in previous communications (1, 3, 6);

2. The high degree of constancy of these determinations is illustrated in Table 4 and in (1), where patients receiving treatment but showing no clinical change, also demonstrated no significant neurochemical change. Also, this second series of 33 cases confirms the observations made in the first series of 24 cases (1);

3. Neither a unitary, nor a biochemical, nor a unitary biochemical basis for all schizophrenic illnesses is necessarily assumed in this paper or in previous communications, and certainly not for all depressive illnesses and chronic brain syndromes. A biological basis (genetic: experiential: biochemical) is assumed;

4. Of 57 cases, both in this and in the previous communication (1), 39 were treated with one treatment alone;

5. Duration of illness, age and sex of patient show no clear relationship to *changes* in glycoprotein constituent concentrations in individual patients. The *basal* level of glycoprotein hexosamine tends to be higher with increasing age, and tendencies for the basal level of glycoprotein hexose to relate to age are also described (1), but no relationship of age, sex, or duration of illness has been observed to either increases, decreases or both in these constituents in the same patient;

6. The conventional schemata of clinical improvement are indeed used here (see Table 1) since, as pointed out in the text, these are generally common stable behavioral data used in every mental status examination. The neurochemical data are therefore here correlated with ordinary detailed mental status data.

PHRENOTROPIC DRUGS IN PSYCHOSOMATIC DISORDERS (SKIN)¹

EVA P. LESTER, M.D., E. D. WITTKOWER, M.D., F. KALZ, M.D.,
AND H. AZIMA, M.D.²

Skin disorders and especially those with excessive itching have attracted great clinical and therapeutic interest in psychosomatic medicine. The trial of phrenotropic drugs in patients with pruritic tensional syndromes or in those with disfiguring chronic eruptions and depressive symptoms offered from the start attractive theoretical and therapeutic possibilities. It, furthermore, allowed the testing of the efficacy of these drugs in a visible and recordable situation. A good number of studies on the subject have been reported over the last six to eight years, but only few among them are controlled pharmacological trials (1-7). The results obtained in these studies vary greatly; this reflects on the difference of orientation in the observers as well as the great variability in the criteria and methods applied by the different investigators.

The present study is a joint effort of three psychiatrists and one dermatologist. The purpose of the study was to investigate: 1) the effects of these drugs on the two components of the disease, *i.e.*, disturbances of mood, behavior and thought; and cutaneous changes and 2) the interrelation of these two separate groups of symptoms during the treatment process. A secondary objective was to develop clinical criteria for psychopharmacotherapy in dermatology with regard to selection of patients, dosage and duration of treatment.

MATERIAL AND METHOD

We shall discuss this under four headings: dermatoses, patients, drugs and assessment of change.

¹ Read at the 117th annual meeting of The American Psychiatric Association, Chicago, Ill., May 8-12, 1961.

² Depts. of Psychiatry and Dermatology, McGill University, The Allan Memorial Institute, and the Royal Victoria Hospital, Montreal, Quebec.

This work was supported by grants from the National Institute of Mental Health (grant MY-2151), Geigy Pharmaceuticals, Hoffmann-La Roche Limited and John Wyeth and Brother Limited.

Dermatoses: Four dermatoses were chosen; atopic dermatitis, seborrheic dermatoses (including acne vulgaris), psoriasis and hyperhidrosis. The three criteria for the selection were: age over 14; absence of a psychotic disorder or mental deficiency; and absence of extensive use of phrenotropic drugs in the past. The patients were referred from the skin department of a large general hospital. They were seen at the skin department by a psychiatrist and a dermatologist. It soon became apparent that, despite the intention to have an unselected cross section of patients, a selection was actually made by the referring dermatologists. Chronic intractable cases with obvious psychosocial problems, and cases that were difficult to manage were referred more frequently by the dermatologists than acute and "simple" cases which responded readily to standard skin treatments.

Patients: A total of 85 patients was referred, 14 of whom dropped out before the end of one trial period, and therefore were not included in the study. There were 40 females and 31 males, with an average age of 35 (youngest 14, oldest 60). Diagnostically they consisted of 25 patients with psoriasis, 18 with atopic dermatitis, 26 with seborrheic dermatoses (including acne) and 2 with hyperhidrosis.

Drugs: Four drugs (chlorpromazine, imipramine, meprobamate and chlordiazepoxide) were used in a double blind fashion. Each drug was tried for 4 weeks. If improvement was effected in the skin condition during this time, the drug was continued for 4 months, after which an identical placebo was introduced for 4 additional weeks. If no improvement was noticed with one drug in 4 weeks the next drug was introduced. Each patient had five 4-week trials or, one 4-month and one 4-week trial. Standard therapeutic doses were gradually increased to the level of individual tolerance. Since these were outpatients, the

maximum dose was often lower than the usual maximal doses for patients treated in psychiatric wards. However, they were considerably higher than the doses used by most non-psychiatric investigators and consisted of: chlorpromazine (100-400 mgm.); meprobamate (1200-3200 mgm.); imipramine (75-150 mgm.); and methaminodiazepoxide (40-100 mgm.). It should be noted that in many instances, particularly in order to increase the patient's motivation for regular attendance, it was necessary to prescribe non-specific local medication.

Assessment of Change: Following the referral by the dermatologist, each patient was seen by the psychiatrist in a long psychiatric interview. The focal points of this initial interview were: 1) the establishment of a relationship between life situations and the onset and subsequent exacerbations of cutaneous disorders; 2) the personality of the patients; 3) the central conflict group and its possible relationship to the cutaneous manifestations. Subsequently the patients were seen weekly by both the dermatologist and the psychiatrist. One psychiatrist conducted all the interviews, but the results were discussed and evaluated by another psychiatrist as well. Photographs of the affected areas of skin were taken at the beginning and the end of each trial period. Two categories of variables were selected for the evaluation of observed changes: 1. Psychological variables consisting of anxiety-tension, and depression; 2. Dermatological variables consisting of rash and itching. Additional variables studied were sleep, other somatic symptoms, patient-therapist relationship and environmental stress.

The grouping of psychological variables into two poles of anxiety-tension and depression was to facilitate the assessment and quantification(9). On the pole of anxiety-tension such symptoms were included as restlessness, agitation, fears, irritability, the feeling of being jittery, panic, the autonomic equivalents of anxiety (palpitations, tremors, dryness of the mouth, excessive perspiration, shortness of breath, a choking feeling), and vague anxiety. On the pole of depression were included sadness, apathy, retardation, apprehension, preoccupation with death, self-recriminations, hope-

lessness, and helplessness.

For the appraisal of dermatological change we chose the variables of rash and itching. By "rash" is meant the objective manifestations of the skin, including exudation, scaling, excoriations, etc., and by "itching" the subjective skin sensations such as the itch proper, burning sensations and tickling. For quantitative analysis of our findings, the four variables were rated on each weekly interview in the order of:

no	0 (the symptom in question is absent)
mild	*
moderate	**
severe	***
very severe	****

The rating was made on the basis of the subjective statement of the patients and the observations of the examiner. Because rating scales were not used, it might be argued that the evaluation of change was somewhat arbitrary. However, our object was not the effect of the drugs on the psychiatric symptoms of the patients, but the relative change of these symptoms and their correlation with changes in cutaneous pathology. We were aware that our method, based entirely on the clinical impressions of a psychiatrist, might include a degree of subjective error, but as long as this error was kept relatively stable, the final results were not significantly affected.

Finally, for the evaluation of change, a comparison was made between the beginning and the end of each drug period. Fluctuations within the period were not taken into account. The change was rated as: worse, no change, little, moderate and excellent improvement.

RESULTS

Table 1 shows the combined effect of the 4 drugs as compared with the effect of the placebo. If amelioration of the rash and/or itching is taken as an indication of effectiveness of any dermatological treatment, the phrenotropic drugs as a whole produced results exceeding a 50% improvement. The results obtained by the placebo approximate a 30% improvement. This is in agreement with most studies on the placebo effect.

If the individual diseases are considered separately, as shown in Table 2, there is no difference between improvement rates in seborrheic dermatoses and psoriasis. Atopic dermatitis shows a slightly higher rate of improvement. This could be explained by the fact that in atopic patients, the existing psychiatric symptoms were, on the whole, more pronounced. Atopic individuals are exceedingly tense, restless, difficult-to-manage patients (10). The presence, since infancy, of a strong predisposition of the skin for exaggerated pruritic responses to a wide variety of stimuli (what is now accepted as the constitutional basis of atopic dermatitis) produced a profound effect on the person-

ality of these patients. The observation made here is that atopic patients, more often than other dermatological patients, present marked disturbances of mood and behaviour and that these respond readily to phrenotropic agents. Concomitant to this, there is a change in the intensity and gravity of pruritus, restoration of other bodily functions such as sleep and appetite and improvement in the pathologic skin manifestations. We can cite briefly one case:

A 38-year-old married woman with generalized rash, crippling itching and a host of other somatic symptoms, all of a functional nature (diarrhea, anorexia, insomnia, weight loss and

palpitation), had been in and out of hospitals and had had a lengthy list of treatments for the last 10 to 15 years. She had spent a great deal of her childhood in foster homes and convents and had a 4-year hospitalization for the eczema between the ages of 7 and 11. She had married at 15, and had 4 children. Her family life was entirely disorganized and the patient expressed the feeling, when she came to us, of a "nightmare without end." Chlorpromazine effected a remission of all somatic symptoms; the skin almost cleared up. On placebo, she relapsed.

Comparing the drugs separately, as shown on Table 3, it is observed that there

the present study does not exceed 50% while the other drugs show better results.

The number of patients studied under Librium was too small to draw valid conclusions. Nevertheless, it is rather surprising that despite a good response to this drug as far as tension-anxiety and pruritus were concerned, the patients showed relatively little objective dermatological improvement. Unless this is a statistical "accident" due to the small number of cases, it is an observation rather difficult to explain in view of the fact that results with the other drugs are uniformly consistent.

Imipramine, an antidepressant, showed

are differences in their effectiveness. Chlorpromazine has a better overall effect. The improvement of the dermatological symptoms effected by chlorpromazine was highly significant in that the probability of it being a chance occurrence is <2.5%. The changes produced by the other drugs have a relatively low statistical value (probability of chance occurrence 5% or more). All drugs produced amelioration of pruritus in more than 50% of their patients which is especially important as pruritus often represents a most annoying and incapacitating symptom. Interestingly, in contrast to previous enthusiastic reports on the antipruritic value of meprobamate, its effectiveness in

moderate results in the overall improvement rates. However, if these are plotted against the number of patients who initially presented signs of depression, then imipramine proves to be effective in skin disorders with depressive components. (Total effect, 57% improvement of the rash and 66% of the itching.)

The response of patients with acne vulgaris to imipramine proved an interesting finding. Of 9 cases studied, 8 presented clinical signs of depression at the time of introduction to the drug. These were young people with acne vulgaris of 6 to 10 years duration, with multiple scars on the face. The prevailing mood was one of hopeless-

ness, apathy and defeat. Most had considerably withdrawn from social contacts, were sensitive to human interactions and harbored feelings of inadequacy and guilt. Imipramine produced complete recovery from these symptoms and initiated dermatological improvement. Cases with moderate rashes cleared entirely and those with severe extended rashes showed considerable amelioration.

An observation made repeatedly during the investigation was that improvement usually was parallel in all four variables. Anxiety-tension and itching usually improved first while changes in the various eruptions took some time to appear. Depression, if present, responded slowly too—a common phenomenon in psychopharmacotherapy. In order to illustrate this correlation between the four variables we plotted each individual trial separately (Figure 1). The figure clearly illustrates that changes in psychiatric pathology went parallel with changes in dermal pathology, in other words, that there was a global response to the drug. Since these drugs are not known to possess specific properties as far as the skin is concerned, we are inclined to believe that the dermatological improvement was due to central mechanisms.

An attempt was finally made to correlate the findings to the personality of the patients. Because the number of cases examined was not very high, it was decided to group them into 4 major categories. (The patients who did not belong to any of these 4 categories are not included below.) This

classification was as follows :

(a) <i>Neurotic disorders</i>	54
Hysteric	14
Obsessive-compulsive	22
Reactive depressive	18
(b) <i>Personality disorders</i>	41
Passive-dependent-inadequate	28
Aggressive-dependent-rigid	13
(c) <i>Prepsychotic disorders</i>	15
(d) <i>"Normal" personality</i>	8

(The numbers represent drug trials on patients with the above disorders.)

If all neurotic disturbances are taken together, there are practically no differences between the groups (a), (b), and (c), as indicated on Table 4. The comparative analysis of the findings among the three subgroups in category (a), however, indicates that subgroup "reactive depressions" showed by far the best results. (Improvement : tension 77% ; rash 88% ; and itching 93%.) If this subgroup is not included in category (a), the results obtained by pharmacotherapy with hysteric and obsessive-compulsive patients are not much higher than the results obtained by placebo. It must be stressed here, that in the category labelled "personality disorders," we did not include psychopathic character disorders, addictions and sexual aberrations, *i.e.*, disorders which are renowned for their resistance to all kinds of treatment. The reason for this is that only a few patients were referred, and these dropped out very early

TABLE 4

in the course of investigation. The patients included as personality disorders were predominately passive dependent, inadequate, chronically anxious persons and these did

remarkably well with the agents used. The 8 patients in the category "normal personality" showed dermatological improvement of less than 20%.

ATOPIC DERMAT.

CONCLUSIONS AND DISCUSSION

A number of dermatological patients suffering from various "psychosomatic" dermatoses and presenting a varying degree of psychopathology were studied over a period of 4 weeks to 20 months. Phrenotropic drugs were administered as the sole or primary therapeutic agent. The following conclusions are drawn from the analysis of the data obtained :

1. All in all, about 50% of the patients showed improvement in the cutaneous symptomatology of the dermatoses studied. The response to placebo did not exceed 30%.

2. There was a good correlation of improvement between the dermatological variables, *i.e.*, rash and itching and the psychiatric variables, anxiety-tension and depression. This correlation was especially marked between tension-anxiety and itching. Previous work has demonstrated that the patients under experimental stress show a reduced threshold for itching(11). The data presented here establish the psychosomatic principle at this level of physiological phenomena. Chlorpromazine proved to have the best anti-pruritic effect. It is significant that imipramine, an antidepressant, has also a marked effect on itching. The response of itching to imipramine as shown from the presented data is relative to the response of depressive symptoms to the drug. This points to the often expressed hypothesis that itching in certain cases is a depressive equivalent. In these cases, patients unconsciously use itching and scratching as an act of self-destruction.

3. An observation made repeatedly was that the effectiveness of the drugs on the cutaneous pathology was relative to the degree of psychiatric symptoms. In other words, patients with severe anxiety-tension or depression, responded best in their skin symptoms. Patients with negligible psychopathology showed little dermatologic improvement.

4. Despite the fact that most of the symptoms rated here as depression were of a neurotic-reactive nature, they responded well to imipramine (total improvement of about 65%), a drug usually considered effective in the major depressions. Its effective-

ness should probably be reappraised, as imipramine is here shown quite active in neurotic-reactive depressions. The antidepressant effect of chlorpromazine should also be emphasized. This finding is in accord with the work of Lambert, Revol(12) and their group in France, who have shown that those phenothiazines which have a sedative effect on anxiety and psychomotor activity, like levomepromazine and chlorpromazine, also have an effect on depression ; the piperazine-like phenothiazines, on the other hand, act mostly on the thought and perceptual disturbances and have little or no effect on anxiety and depression.

5. In 12 cases of acne vulgaris, we found 8 patients with depressive symptoms. These responded markedly well to imipramine. The improvement of mood was always followed by dermatological improvement. Antidepressants have already been used in chronic somatic illnesses such as rheumatoid arthritis, asthmatic bronchitis and others, mainly to supplement steroid or other physical treatments(13, 14). The reported results indicate that antidepressants add an important dimension in the treatment of these disorders. The proposed basis for their effectiveness is that energy deflected on to the self is freed by the drugs and redirected to the outside world(15). The use of antidepressants seems equally justified for chronic diseases with disfiguring and emotionally crippling effects on the self, which are very frequently accompanied by severe reactive depressions. These depressions have long been overlooked, either because they are masked by somatic symptomatology or because they are considered by many physicians a "natural" reaction to a crippling illness.

6. With regard to psychiatric diagnosis, skin patients with depressive symptoms showed a marked dermatological improvement with phrenotropic drugs. Patients with personality disorders of the passive-dependent and aggressive-dependent types, as well as prepsychotic disorders did well also, while neurotic patients (without depression) did poorly.

A COMPARATIVE STUDY OF SELECTED ANTIDEPRESSANT MEDICATIONS AND EST¹

MILTON GREENBLATT, M.D., GEORGE H. GROSSER, Ph.D.,
AND HENRY WECHSLER, Ph.D.²

In studies testing the efficacy of psychotropic medications there has been a trend toward the use of larger samples under better controlled double blind conditions. More and more knowledge is being accumulated concerning overall rates of improvement on specific medications. However, at this stage of research, measures of treatment outcome are mainly confined to global clinical ratings of improvement, or to changes in discrete symptoms. The use of global ratings, although indispensable in psychiatric assessment, tends to obscure differences in the effectiveness of medications in various areas of behavior and functioning. A quest into the specificity of drug action in terms of both types of behavior and types of patients affected is the next necessary step in the refinement of psychopharmacological research.

An increasing number of studies employ a control group on placebo in evaluating the efficacy of one or two active medications. This may indicate whether or not a psychotropic drug may produce significantly better results than a nonactive compound. However, few studies have attempted to compare psychotropic medications with older, already established forms of somatic therapy. This is of particular importance in the affective disorders, where EST has been used so prevalently with reported effectiveness. What the practicing clinician would

like to know, in reference to the depressions, is not only whether a given antidepressant medication is significantly more effective than placebo or chance, but whether it is equally or significantly more effective than the best somatic treatment currently available, and, if so, for what types of patients and for what predominant types of disturbance.

The current study compares 3 antidepressant medications with EST in terms of several qualitative and quantitative measures of treatment outcome, under controlled conditions. It also presents differential results for selected patient groups.

THE RESEARCH DESIGN

The data here presented have been accumulated during the course of an interdisciplinary multihospital drug testing project conducted in 3 state mental hospitals in the Greater Boston area. Data were processed and analyzed by a central team, which was also responsible for the standardization of procedures and development of instruments for assessment of patient change. A research team in each of the 3 collaborating hospitals was in charge of the treatment of the patients and the collection of data.

All patients included in the project at the 3 hospitals were randomly assigned to 4 treatment groups and (with the exception of EST, which could not be disguised) treated under a double blind design. The treatment period for each of the groups lasted for 8 weeks, although patients could be discharged from the treatment phase of the project after the fourth week if, in the opinion of the physician, they were sufficiently improved to leave the hospital and function in the community. Each patient is currently followed for one year upon discharge for informational purposes. This report is based on results obtained with the first 128 patients during their 8-week treatment period.

(a) *Treatment program.* Three drug

¹ The study, entitled *Drug Treatment of Depressed Hospitalized Patients*, is under sponsorship of the Massachusetts Mental Health Center, Boston, and financed by a grant (MY 3314) of the Psychopharmacology Service Center, Bethesda, Md. Principal investigators are Milton Greenblatt, M.D., Harry Freeman, M.D., Edward Meshorer, M.D., and Morris Sharp, M.D. Research coordinator is George H. Grosser, Ph.D. The authors are greatly indebted to the collaboration of about 40 members of the research teams at Medfield, Metropolitan, and Westborough State Hospitals for their contribution to the project.

² From the Massachusetts Mental Health Center, and the Dept. of Psychiatry, Harvard Medical School.

groups were used and compared with a group on EST. The drugs and dosages were as follows :

isocarboxazid (Marplan) : maximum obligatory dose 40 mg., with another 10 mg. optional ;

phenelzine (Nardil) : maximum obligatory dose 60 mg., with another 15 mg. optional ;

imipramine (Tofranil) : maximum obligatory dose 150 mg., with another 37½ mg. optional.

Dosages were gradually increased so that maximum dosage was reached in the third week. EST, modified by anectine, was given with a minimum of 9 treatments (3 times weekly for 3 weeks), with further treatments at the discretion of the project psychiatrist.

In order not to contaminate the effects of our treatment program with other treatment given in the hospitals, personnel were instructed not to conduct psychotherapy, casework, occupational therapy, or ancillary therapy with project patients. The latter were housed together but on the same wards as other hospital patients. At 2 of the hospitals these were the male and female acute treatment wards, at the third hospital the research building. As far as possible, all project patients were treated as any other hospital patients.

(b) *Selection of subjects.* All new admissions to the 3 hospitals during the study were screened for participation in the project. Any patient with clinical symptoms of depression sufficiently severe to warrant treatment was considered eligible. The specific underlying dynamic nature of the illness and diagnostic category of the patient was not used as a basis for selection. As a consequence, psychoneurotic and psychotic depressive reactions ; manic-depressive psychoses in the depressed stage ; involutional psychoses ; schizophrenic reactions, schizo-affective type ; and personality disorders with depression could be included. All such patients between the ages of 16 and 70 were admitted to the study with the following exceptions :

1. Patients with severe organic impairment or physical condition which would contraindicate any of the treatments to be used ;

2. Patients requiring other types of maintenance treatment during the study (e.g., insulin or cortisone) ;

3. Patients with drug or alcohol addiction in addition to the depression ;

4. Patients who had been treated with antidepressant medications or EST within a month of admission.

Between March 16, 1960, and April 30, 1961, 151 patients were admitted to the study. Of these, 23 did not remain in treatment for the required minimum period of 4 weeks. The 15% drop out rate was due to medical complications, and to patients leaving the hospital against physicians' advice.

(c) *The patient population.* This was composed primarily of females, with a sex ratio of 3 to 1. The mean age for both sexes was 46, with only 12.5% of the patients below the age of 30, and 50% of the patients between the ages of 50 and 70. In terms of diagnostic categories, most of the depressed patients were classified as psychoneurotic depressive reactions (24%), schizophrenic reactions, schizo-affective type (24%), manic-depressive reactions (20%), and involutional psychotic reactions (15%).

Most of the patients had been hospitalized before, with approximately one-third hospitalized 3 or more times prior to this admission, one-third hospitalized 1 or 2 times, and only one-third first admissions.

Patients at the 3 hospitals were very similar in terms of these and other social characteristics. Most patients were housewives of lower middle or upper lower socioeconomic status. The majority had not completed high school, and their husbands worked in service, semi-skilled, or skilled manual occupations. The religious composition of the patients corresponded with the composition of their communities, with a predominance of Roman Catholics. Since the 3 hospitals draw their patients from 50 communities in the Greater Boston area, nearly all patients were from these urban or suburban centers. The population was white with the exception of one patient.

ASSESSMENT OF RECOVERY

For a full assessment of recovery an attempt was made to use a variety of measures which would cover different areas of

patients' mental status and functioning. The measures included:

(a) *Global rating of recovery.* This involved the usual 3-point rating employed in studies of this kind, on the basis of which patients were differentiated as to whether they had improved significantly, moderately, or not at all. This rating was made by the central team of the study on the basis of reports submitted by the project physician and a psychiatric examination of each patient at the end of the treatment period. The rating was made without knowledge of the type of treatment which the patient received.

The patient was judged markedly improved if he was viewed as ready to be discharged from the hospital and capable of resuming familiar community roles; moderately improved if some degree of improvement was discernible, although not sufficiently marked to permit the patient to be immediately discharged; and unimproved if he failed to show any appreciable change, experienced deterioration, or if his improvement was so slight that in terms of practical adjustment, management of tension, and ability to function, the change was insignificant.

(b) *Mental status.* Mental status examination protocols were analyzed to yield a quantitative score of the number of symptoms before and at the termination of the treatment. The scale consisted of 19 items, the majority of which recorded the presence or absence of symptoms. Maximum possible score on the scale is 55 points, minimum is 19. A method was devised to prorate the total score for items on which information was missing.

(c) *Measurement of depression.* A Depression Rating Scale was specially constructed for the project to measure the extent of clinical depression. It consists of 28 4- or 6-point scaled items covering the following areas: 1. Patient's assessment of his own psychological state; 2. Patient's assessment of physical and motor functions; and 3. Physician's assessment of the patient's condition.

The scale is completed by the project physician on the basis of a psychiatric examination. It has been found to differentiate between depressed patients, nonde-

pressed schizophrenic patients, and normal controls. A reliability analysis has indicated a high degree of agreement between psychiatrists who independently rate the patient.³

The maximum possible score on this scale is 145, the minimum 28. Total scores were adjusted through prorating for items marked not ascertainable.

(d) *Behavioral measures.* Patients' behavioral changes during the treatment period were measured by means of a Ward Observation Inventory. This is a 33-item, 4-point scale covering the areas of patient attitudes to hospital and medical routine, patient-personnel interaction, patient-peer group behavior, and patient activities on the ward. This instrument is filled out by trained ward nurses, who are assigned to observe patients at regular intervals. The maximum possible score on this is 134, the minimum 33.

The 4 instruments employed, therefore, provided both a qualitative overall assessment of change and more detailed quantitative scores for symptoms, depressed mood, and ward behavior.

RESULTS

(a) *Global ratings of recovery.* Fifty percent of the patients were found to be markedly improved, 25% moderately improved, and 25% unimproved. These rates were constant at each of the 3 participating hospitals.

Table 1 presents global ratings of recovery by treatment program. It may be seen that 75% of the patients treated with EST were found to be markedly improved as compared with 50% of the patients on phenelzine, 46% on imipramine, and 33% on isocarboxazid. A chi-square analysis reveals that EST produced significantly more marked improvements than isocarboxazid ($p=.01$) and imipramine ($p=.05$). EST also produced more marked improvement than phenelzine, but this only approaches significance at the .1 level. There were no significant differences among the 3 drugs, with the exception that phenelzine pro-

³ Details concerning this measure, as well as the Ward Observation Inventory, will be published in a forthcoming paper on methodology, *The Methodology of Drug Evaluation In Depression*.

TABLE 1
Clinical Ratings of Treatment Outcome by 4 Treatment Programs

	EST	TOFRANIL	NARDIL	MARPLAN	TOTAL
Markedly improved	21 (75.0)	17 (46.0)	15 (50.0)	11 (33.3)	64 (50.0)
Moderately improved	4 (14.3)	10 (27.0)	10 (33.3)	8 (24.2)	32 (25.0)
Unimproved	3 (10.7)	10 (27.0)	5 (16.7)	14 (42.4)	32 (25.0)
Total	28	37	30	33	128

duced more marked improvement than isocarboxazid at the .1 level.

When marked and moderate improvements are combined, EST is seen to produce some degree of improvement in 89% of the cases, phenelzine in 83%, imipramine in 73% and isocarboxazid in 57%. In this case, a chi-square analysis reveals that the only significant difference is between EST and isocarboxazid ($p=.05$). Phenelzine also produces more moderate and marked improvement than isocarboxazid, but this is only significant at the .1 level.

In order to examine the higher rates of marked improvement under EST in comparison to the drugs, an analysis of the outcome for certain categories of patients on EST and drugs was made.

1. *Treatment outcome by sex.* Table 2 presents treatment results in terms of global ratings of recovery by EST and drugs separately for each sex. It may be seen that 47% of all females improved markedly as compared with 58% of all males. This dif-

ference is not statistically significant. For the males on EST and on drugs there appears to be no difference in treatment outcome, with both forms of treatment producing the same remission rates. However, in the females 80% improved on EST as compared with only 39% on the antidepressant drugs. A chi-square analysis reveals that significantly more females improved markedly under EST than under the drugs ($p=.01$).

2. *Treatment outcome by age.* In Table 3, when patients were divided into 3 age groups, it was found that 62% in the youngest age group improved markedly, 40% in the middle age range and 47% in the oldest age group. A chi-square analysis revealed that significantly more patients in the youngest group improved markedly than in the other 2 age groups ($p=.05$).

While drugs and EST worked almost equally well for the youngest age group, EST seemed to work better in the oldest age group when compared to the medications. The difference in outcome was statistically significant ($p=.05$). In addition,

TABLE 2

Unimproved	4 (8.9)	18 (40.0)	10 (26.3)	32
Total	45	45	38	128

although the frequency of marked improvements was similar for all 3 age groups under EST, this was not the case with the antidepressant medications. These produced significantly better results in the youngest age group than in the 2 older groups ($p=.05$).

3. *Treatment outcome by diagnostic category.* It may be seen in Table 4 that almost all psychoneurotic depressive reactions, approximately half of the manic-depressive and involuntal reactions, and about one-third of the schizo-affectives and psychotic depressive reactions improved markedly.

TABLE 4
Clinical Rating of Treatment Outcome by Treatment Method and Diagnosis

DIAGNOSIS	TOTAL	DRUGS		
		MARKEDLY IMPROVED	MODERATELY IMPROVED	UNIMPROVED

Schizophrenic	31	9 (29%)	15 (48%)	7 (23%)
Depression with personality disorder	10	5 (50%)	2 (20%)	3 (30%)
Total	128	64 (50%)	32 (25%)	32 (25%)

Where patients were combined into 3 major diagnostic groupings—endogenous depressions (comprising the manic-depressive and involuntal categories), exogenous depressive reactions (comprising psychoneurotic depressive reactions, psychotic depressive reactions and depression with personality disorder) and schizo-affective depressions—it may be seen that 66% of the exogenous depressions, 45% of the endogenous depressions, and 29% of the schizo-affective depressions improved markedly. Exogenous depressions have a significantly greater number of marked improvements than both endogenous ($p=.05$) and schizo-affective ($p=.01$).

When drug and EST patients are compared, it is seen that in almost every diagnostic category a greater proportion of patients on EST improved markedly as compared to patients on antidepressant medications. When patients are once again categorized into the 3 major diagnostic

groupings, only in the case of the endogenous depressions is there a significant difference between EST and drugs in terms of number of marked improvements ($p=.05$).

(b) *Symptom remission.* At the end of treatment quantitative scores derived from the mental status examination were studied by means of a covariance analysis to take into account slight differences in the pre-treatment scores. The following results were obtained (see Table 5):

1. Patients treated with EST had significantly fewer symptoms at the end of treatment than patients treated with isocarboxazid ($p=.01$), and had fewer symptoms than patients treated with phenelzine ($p=.1$).

2. There was almost no difference between EST and the imipramine groups on this measure.

3. There were no significant differences among the 3 drugs. However, patients

MS: Mental Status Symptom Rating

DRS: Depression Rating Scale

WOI: Ward Observation Inventory

* To account for initial differences on means covariance technique was employed as described in McNemar, Q.: *Psychological Statistics*. New York: John Wiley & Sons, 1949, p. 318.

treated with imipramine had fewer symptoms at the end of treatment as compared with patients treated with isocarboxazid ($p=.1$).

In general, patients on EST appeared to have the lowest number of symptoms at the end of treatment, patients on isocarboxazid the highest, and patients on phenelzine and imipramine in the middle.

(c) *Changes in clinical depression as measured by the Depression Rating Scale.* When Depression Rating Scale scores of the 4 treatment groups were studied before and at the end of treatment, a covariance analysis revealed that (see Table 5) :

1. Patients treated with EST had significantly lower scores at the end of treatment than patients treated with isocarboxazid ($p=.01$) and phenelzine ($p=.01$).

2. There were no significant differences between the EST and imipramine groups.

3. Once again, patients treated with imipramine had lower scores than patients treated with isocarboxazid, though not significantly lower ($p=.1$).

As in the case of symptom measurement, patients treated with EST had the most successful outcome in terms of the Depression Rating Scale. Those treated with isocarboxazid had the least successful outcome; of the drugs, imipramine appeared to have produced the most successful outcome.

(d) *Changes in ward behavior.* A covariance analysis of ward behavioral data at the end of treatment reveals that (see Table 5) :

1. Patients treated with EST were significantly less disturbed in their behavior at

the end of treatment than patients treated with each of the 3 drugs (EST compared with isocarboxazid, $p=.001$; with phenelzine, $p=.02$; with imipramine, $p=.05$).

2. There were no significant differences among the 3 drugs.

This measure also reveals EST to be most successful, isocarboxazid least successful, and phenelzine and imipramine somewhere in between in terms of changing patients' behavior on the ward.

(e) *Intercorrelations of the various measures.* It can be stated that all 4 measures—global rating of outcome, symptom measure scores, Depression Rating Scale scores, and Ward Observation Inventory scores—point to the same general conclusion: on each measure EST appears to produce the best results, while isocarboxazid appears to effect the least change in the patient.

Table 6 indicates how the global ratings of improvement are related to the 3 quantitative measures. In all cases except for the Ward Observation Inventory scores, the improved, moderately improved, and unimproved patients start with approximately the same score before treatment began, but end with significantly different scores. In the case of the ward behavior measure, the patients, in addition to ending with significantly different scores, also reveal significantly different scores in the pretreatment period. Here the differences between the improved patients and patients who were moderately improved or unimproved at the end of treatment are significant before treatment began, suggesting, perhaps, a poorer prognosis for patients with

MS and WOI	.45	.81

cant correlations between the Depression Rating Scale, the Ward Observation Inventory, and the mental status symptom rating, both at the beginning and at the end of treatment. The correlations are much higher at the end of treatment, due perhaps to a "halo" effect.⁴

(f) *Side effects.* A side effects protocol was administered by project physicians weekly during the course of treatment as well as during the pretreatment period. Symptoms which were reported or observed during the treatment period⁵ but were not also present before treatment began were considered as side effects and are presented in Table 8.

Although, as is indicated by the table, a considerable variety of side effects was recorded in the study, each side effect was present in only a small number of patients on the various treatment programs. In addition, with very few exceptions, side effects were transient and of a nonserious nature.

Specifically, the following side effects appeared in approximately 20% or more of the patients under each treatment:

⁴ A general awareness on the part of personnel that a patient was markedly improved and his discharge was imminent may have influenced them to rate the patient as "healthier" on some items.

⁵ A detailed analysis of the differences between symptoms of depression ("quasi" side effects) and side effects of medications ("true" side effects) was presented by Busfield, B. L., M.D., Capra, D., M.D., and Schneller, P., M.D., entitled, *Depressive Symptom or Side Effect? A Comparative Study of Symptoms During Pretreatment and Treatment Periods on Three Antidepressant Medications*, annual meeting, APA, Chicago, May 1961.

EST :	headaches, anorexia
isocarboxazid :	shakiness, sweating, weakness, drowsiness.
phenelzine :	dry mouth, sweating, drowsiness, weakness, shakiness, bowel dysfunction
imipramine :	drowsiness, dry mouth, urinary frequency, bowel dysfunction

Of the side effects which could be considered potentially serious, the only observed cases were: one possible convulsion, one choreiform twitch. No hepatic, renal, or serious cardiovascular involvement appeared.

Hypotension has been such a frequently observed side effect that it deserves special comment. We considered a patient hypotensive if his previous normotensive systolic pressure dropped below 80 or if his pretreatment level of equal or greater than 135 experienced a drop of 15% to 25%. Analysis of hypotension in the 4 treatment programs revealed that patients on EST as well as those on each of the antidepressants commonly developed transient hypotension—16% of those on EST, 27% on isocarboxazid, 30% on phenelzine, and 50% on imipramine became hypotensive, but in only one case was this severe enough to cause change of the treatment. In our series, development of hypotension was not dose related; treatment ordinarily consisted of stopping medication for 1 or 2 days to resume it subsequently. In some cases it was felt that treatment could continue uninterrupted, with no harmful consequences.

Analysis of 12 patients dropped for medical reasons among 130 patients reveals only one for hypotension on imipramine. Emergence of other psychopathology was seen in 8 patients, with 2 developing hypomania, 2 anxiety, and 4 disabling symptoms of thought disorder, chiefly paranoid ideation and autism. Worsening clinical course of depression with development of suicidal drive and acidosis in 3 patients on drugs necessitated intervention with EST. Weekly laboratory determinations including hemoglobin, hematocrit, WBC, urinalysis, alkaline phosphatase and bilirubin revealed only transient alterations unrelated to the patient's clinical course on antidepressant medication or shock.

TABLE 8
Reported and Observed Side Effects

SUMMARY

The effectiveness of 3 antidepressant medications was compared with that of EST in 128 depressed hospitalized patients at 3 state mental hospitals. The results of this double blind study employing 4 different measures of treatment outcome present a consistent trend. They indicate that :

1. In this sample, the 4 treatments produced 50% marked improvement, 25% moderate improvement, and only 25% minimal improvement or lack of response. Although

the absolute number of patients in the 3 hospitals differed, no appreciable deviation from this distribution was found in any of the 3 institutions.

2. There was no difference in treatment outcome between the 33 males and the 95 females. However, patients in the 16-39 age group showed more marked improvements than older patients. In addition, exogenous depressions responded significantly better to the 4 somatic treatments than schizo-affective and endogenous patients.

3. Patients treated with EST manifest a higher degree of improvement than patients treated with the 3 antidepressant medications. Specifically, a higher proportion of EST patients improved markedly than patients on drugs. In terms of symptom remission, decrease of depressive affect, and decrease in behavioral disturbance, EST patients in general fared better than the other patients. However, this was significant in all cases only in comparison to patients treated with isocarboxazid. Patients treated with imipramine revealed on several of the measures higher degrees of improvement than patients treated with the 2 MAO inhibitors.

4. When EST patients were compared with all drug patients to study selectivity of the 2 somatic treatments, it was found that younger patients, male patients, and patients with exogenous and schizo-affective depressions appeared to do as well on drugs

as on EST. In the case of females, older patients, and endogenous depressions, EST showed significantly more marked results than the antidepressant medications.

5. The 4 measures were very consistent in revealing this pattern of results, with one exception: phenelzine appeared to show a higher degree of effectiveness as measured by the global ratings of outcome than as measured by the 3 quantitative indices. More cases will be required to account for this discrepancy. In other respects, the 3 quantitative measures showed very high intercorrelations, and were strongly related to the qualitative ratings of treatment outcome.

6. A relatively low frequency of side effects was recorded during the course of the study. These were largely of a transient nature, and not dose related.

FAMILY CARE OF THE MENTALLY ILL IN NORWAY

JOHN EISELE DAVIS, Sc.D.¹

The Dikemark Mental Hospital, one of the largest in Norway, has a patient population of 800. Outside the hospital in nursing homes are approximately 950 general medical, surgical and senile patients. There are, in addition, about 950 patients in family care. Both of these groups are under the medical supervision of Dr. Arne Sandbu, staff psychiatrist at the Dikemark Mental Hospital and an imaginative and conscientious specialist in home care whose psychiatric horizon has extended to conferences and studies with Jung in Switzerland and Dr. Walter McClay in England. In another mental hospital at Lier, Norway, there are approximately 175 patients in private care as compared to more than 800 in the hospital. Throughout the entire hospital system in Norway there are more patients being cared for and treated outside the psychiatric hospitals than in these institutions. With the exception of the approximately 2500 patients at Geel, Belgium, the numbers in private care in Norway exceed on a population basis those in any other country.

This stress on care outside the institution reflects a social philosophy of mental treatment and rehabilitation which is bound to attract the interest of hospital administrators in other countries who are attempting to bring this problem back to the community and to organize all practical resources at this level, especially at this time when the public is being awakened to its opportunities and responsibilities for effective social rehabilitation.

This impressive innovation in the balance between institutional and home treatment characteristic of the Norway health system appears to be the result of many and varied factors including the basic personality of the Norwegian, the historical evolution of his hospital system and the steady growth of social appreciations and practise emanat-

ing from both a realistic and idealistic leadership.

In discussing this problem with Dr. Carl Evang, Director General of Health Services, the writer expressed the opinion that the unusual support of the public in these mental health improvements in Norway was due to the strategy of providing intensive orientation of the public leading to the situation in which the man on the street *requests* a constantly higher plane of services rather than the opposite situation in which a medical hierarchy tells the public that they *should have* these services. Dr. Evang stated that while the medical authorities constantly aimed to inform and stimulate the public, it was the personality of the Norwegian himself, his incessant desire to improve, to help himself, to measure up to the social opportunities of a new world that accounts in a large measure for the consistent progress of Norway's health system. He accepts these social aims as legal and moral rights to be exercised or lost.

Dr. Lohne Knudsen, director of the psychiatric division of The Health Services of Norway who has been a most important factor in the current developments and philosophy behind the home care services, reminds us of the evolutionary changes in the laws pertaining to extramural care and treatment.

The Frostating Law in the 10th century was the oldest edict in Norwegian legislation which decreed that anyone could freely bind an insane person, take him to court (Ting), and there deliver him to his relatives who were obliged to take over the responsibility for him. The first asylum in Norway was founded in 1741. It was in the prison of Christiania together with a poor house. Only later in the 18th century, and after Pinel broke the shackles of the insane, and Esquirol worked out plans for separate institutions, asylums in Norway began to take on the appearance of hospitals. But during the Middle Ages, the majority of the mentally ill were dependent upon care outside institutions. In Norway, as in other

¹ 1960 Fulbright Professor, University of Oslo; Exec. Dir., Association for Physical and Mental Rehabilitation, 105 St. Lawrence St., Rehoboth Beach, Del.

countries, confinement in small dark rooms for years, even cellars and barns, was the general practise. The supervision of doctors was not considered necessary. An account given by Professor Frederik Holst in 1828 of the general conditions of the insane in Norway shows that of the 1909 certified insane, 72 were in the 7 existing "madhouses," the rest were cared for by their families or by strangers or boarded out by the parish as paupers. In the census taken in Norway in 1845, there were 4290 certified insane persons, and of these about 3000 were placed in private custody by the charities, about 1000 were in temporary lodgings as paupers, while only 147 were in the "madhouses." It was therefore most natural that Dr. Herman Wedel Major considered it of the utmost importance to bring the family care system under control by the Lunacy Treatment Act he proposed in 1848 and enacted into law by the Norwegian Parliament. This law included the interdiction against any person being confined in custody without his being reported to an authorized doctor whose duty it was to investigate whether the precautions were justified and adequate. The Act also included rules enforcing the payment of care and treatment by the authorities of the town or province. An act of 1891 provided for better regulation and supervision and payment by the state of four-tenths of patients' care. These changes laid the foundation for the construction of new hospitals and the improvement and expansion of the old hospitals.

Dr. Harold Arnsen, in an article in the *Journal of The Norwegian Medical Association* in 1907, opposed the expansion of Norway's asylums which had only 2209 beds in 1905 in these words: "For a population such as ours composed mainly of farmers where rural buildings are only in exceptional cases concentrated in villages, family care is the most natural, the cheapest and the best care for the patients in question."

In 1913 a committee was appointed to revise the lunacy treatment legislation. This committee was in definite opposition to all insane persons being cared for in hospitals, and added that family care must be supervised by the medical authorities. It con-

sidered that more than 3 persons in a home was undesirable. The suggestions of this committee were made a part of an appendix to The Lunacy Treatment Act of 1848 which authorized family care, and payment terms were regulated by an additional act of June 5, 1925.

There have always been many insane persons under extramural care, but only during the last 10 years has the figure reached about half the number of all certified mentally disordered persons.

There were, in December 1953, 6057 patients in all under this form of care; 40% of these were in family care within their home district, a further 30% within their home province, while about 30% were boarded out outside their province. The latter was the case especially of patients from Oslo and Bergen, two of the largest cities in Norway. More than 50% are found in one-patient homes.

More important than pre-care is after-care to assist patients to meet the adjustments in the community and remain outside. In 1952 Dikemark Hospital opened an aftercare office in Oslo. These efforts have been organized and legalized by The Mental Health Act of April 28th, 1961 (see Addendum). As part of this plan, aftercare hostels are being planned with accommodation for 10-25 patients, open so that patients can come and go, but are, at the same time, under supervision.

With these responsibilities, the mental hospital becomes the center of greater psychiatric activities which embrace all the care of the patient from the onset of his illness until he is cured or improved so as to be able to manage himself in the community.

The cost of keeping a patient in a family runs between 300-350 Kroner per month, not including clothing and medication. The cost in the hospital is approximately 30 Kroner a day, about three to four times as much as in the private family. The nursing homes in Norway are comparatively new, added to the hospital system during the past 10 years. Each home in Oslo, costing about 600,000 Kroner, is built by a private party with a loan from a private bank guaranteed by the City of Oslo; 15000 Kroner must be paid on the principal yearly on the

5% or 6% loan. The cost per patient in these nursing homes is higher than in private homes—20 to 25 Kr. per day exclusive of clothing and medicine.² The state pays four-tenths and the municipality of Oslo pays six-tenths of the cost of operation. The nursing homes are controlled by a husband and wife, either of whom must be a registered nurse. The male head is termed a Deacon and the woman head a Matron. Twenty patients are treated in each of these homes. There are 7 working personnel: the Matron and husband, or the Deacon and wife, a cook, a nursing aide and 3 maids. There are 10 new homes, all of the same standard type of architecture, two stories, plain, straight yet attractive lines. The homes are furnished with Norwegian furniture, functional and most comfortable; they are immaculately clean and the housework is most efficiently organized. Well ventilated, they are situated so as to afford a fine view of the surrounding country.

The regulations for the family care of The Lier Mental Hospital contains the following provisions: the guardians—only men and women can be chosen who are suited for it and who are known as able and respectable persons. They must be temperate and of good moral character and capable of giving the patients suitable work or keeping them otherwise occupied.

Applications for sanction as a guardian are sent to the medical superintendent of the hospital on a form outlined by the Ministry of Health. If satisfactory, the guardian and his home are then sanctioned by the hospital's Board of Control following the proposal by the medical superintendent. A written authorization detailing the number of patients is then given to the guardian. A contract will be made concerning the guardian's compensation for each patient, based on the patient's condition and ability to work and also the conditions in the proposed home, whether the patient would have a single or double room, *etc.* Three rates, depending upon the patient's work level and whether he requires nursing care, are provided. The contract can be cancelled by the medical superintendent if he finds

the patient not suitable for home care or that the condition of the home or the personality of the guardian is inimical to the treatment.

The guardian is obliged to give the patient suitable accommodations, keep his room sufficiently heated, and give him adequate and good food. He must keep the patient's clothes clean and in good condition. Not more than 3 patients can be taken into one home at the same time, but under special conditions, 5 may be allowed. Where there are more than one patient, they must be of the same sex. The bedrooms must be big and light so that at least 36 sq. ft. of floor space and an average height of 6 ft. (*i.e.*, 216 cu. ft.) are available for each patient who is sleeping in the room.

The rooms must be attractively decorated and properly equipped with beds and other necessary furniture. Where there is no running water or wash basins, each patient must be provided with a basin and two towels. Patients must be properly protected from fire or other emergency.

The Norwegians are very good housekeepers and insist upon cleanliness above all. The patients' rooms must be aired daily and the floor washed. The guardian must see that the patients keep themselves clean. The patient must be given at least 3 main meals a day and coffee in the afternoon. The guardian must take care that the patients eat sufficiently. Any form of alcohol is strictly prohibited.

As far as possible, the patients must be treated as members of the family, must have the same food as other people of the house, and at the same time, and preferably with the rest of the family. It is the guardian's responsibility to see to it that the patients must be encouraged to take part in the daily work together with the people in the house. Care must be taken that they receive necessary rest. The guardian must set a good example to the patients in becoming and controlled behavior. They must deal with the patients in a quiet and kind manner, and try as far as practicable to accommodate themselves to the patient's peculiarities. They must win the patient's confidence and devotion but at the same time see that they are respected. Any form of punishment is strictly prohibited.

² The currency exchange rate of the Norwegian Kroner is approximately a little over 14 cents to the American dollar.

Each home should have the supervision of a doctor and nurse at least once a month. The nurse inspects their clothing, room, boarding, *etc.* She should weigh the patient at least once every 4 months. When necessary, the Board of Control or its individual members will inspect the homes. The patients have an opportunity of bringing any complaints to the Board.

Effective supervision is looked upon as requiring more than control but, in addition, support and assistance, motivation and stimulation for socializing efforts. The second major problem in the nursing homes especially is the lack of stimulating activities ; there is too much sitting around. This situation is being remedied by the provision of an occupational therapist. In the United States this problem could be well taken care of by the employment of a corrective therapist whose training includes both therapeutic exercise and psychiatric socialization. There are also a few of those boarded out who are unfitted for home life because of periodic disturbances and uncleanness. The ideal number of patients for the private home is 1 and not more than 2, because in some rare cases a greater number creates a weakness in the system.

Another indirect problem which contributes to the weakness of the Norway system is the result of overcrowding in the hospitals. In Norway there are only 19.2 approved beds in mental hospitals per 10,000 inhabitants. Since there are 50 mentally sick per 10,000 population, this situation creates a pressure to refer to private homes patients who should go to hospitals. This imbalance is being overcome by present plans for increased hospital bed capacity.

Still another problem which is being attacked as a problem of behavioral science has to do with the psychiatric evaluation of the patient's suitability for home care. Benefitting by early trial and error experiences and after consultation with others in this field both in Norway and abroad, Dr. Sandbu has organized a detailed personality inventory in line with Adolf Meyer's psychobiologic approach to an understanding of the life history of the individual, detailed in The Phipps Personality Inventories, Johns Hopkins Hospital. Information is elicited as

to the individual's ability to care for his daily needs, feeding, dressing himself, sleeping habits, his general orientation, his attitudes, the level of his activity, his interests, working level and adjustment indices. More searching information is sought as to any manifestations of psychotic behaviour that would affect his competency for private care. These areas of diagnosis and prognosis are opening a challenging and rewarding area of psychiatric information at the behavioral level and in the words of one of the psychiatrists "are adding to their social sophistication."

The hospital in Norway appears to assume a more specialized function than a centralized treatment center. One who views its evolutionary growth and development is impressed with its early roots in extramural concepts. Before the organization of hospitals, it was found necessary, as has been pointed out, to place the "lunatic" in the home. This early practise led to the development of home care as a part of the social climate and culture, gradually formalized in the legal enactments which made it obligatory that society assume this responsibility. With the more scientific organization of mental hospitals throughout the world and the centralization of consequential increased treatment facilities in Norway's mental institutions, it would seem quite natural that this country would return the responsibility for full treatment and rehabilitation to the hospital. Norway has countered this trend prevalent in so many parts of the world, and it is this difference which offers a challenge. Today, in Norway, the mental hospital functions as a treatment center for the acutely disturbed and the chronic patients ; added to this is its progressive and significant function as a diagnostic and prognostic agency, a clearing house for those who can benefit by care in the home outside the institution. Once the patient is assigned to the home, the hospital assumes the pivotal responsibility to provide careful medical supervision for him and the home, and in this way extends its practical treatment and teaching influence into the community.

The psychiatric aim and stress is to keep the patient out of the hospital, and the growth of the simple yet functional influences

in what William Shirer calls "a pure democracy" has created an atmosphere in which it seems only natural to allow the mentally sick "to go back home." The modern conflict between institutional versus non-institutional psychiatric care and rehabilitation in Norway seems to be decided in favor of the home, and it might be added that this decision meets with the full approval of its citizenry.

BIBLIOGRAPHY

Knudsen, C. H. : *The Care of the Mentally Ill Outside the Hospital*. The Norwegian Psychiatric Society. Copenhagen : Ejnar Munksgaard, 1956.

ADDENDUM

Current plans for the development of Norway's mental health services are incorporated in the new Mental Health Law which was passed on April 28, 1961 and made effective as of July 1, 1961.

In general the law provides psychiatric pre-care, examination, treatment and aftercare. Every county is given the responsibility for the formulation and presentation of a plan for a complete psychiatric service for its citizens. Final authorization of the plan must be made by the King.

Costs of construction of psychiatric facilities in accordance with the authorized plan to the end of 1965 will be paid by the state, the county or private health associations, the state paying 75% and the county or private health associations the remaining 25%. The maintenance cost will be carried by compulsory sick insurance as long as the patient is recognized as a treatment obligation. When the patient is considered chronic his treatment cost is paid by a special fund from the disabled person's insurance. One of the most significant accomplishments of the new law from the social and economic standpoint is the parity afforded the mental patient, erasing the previous discrimination between the physically and the mentally sick as to apportionment of funds for their care and treatment. Mental patients in private care and in nursing homes will be included in the legal category of chronic patients receiving

medical control and supervision from the local mental hospital. When necessary and without undue legal process they can be brought back to active treatment in the hospital; private care and nursing becoming a part of the mental hospital responsibility through legal enactment. In the event that the patient in private care is far removed from a mental hospital the county psychiatrist assumes the responsibility of his supervision.

A most important committee, the Board of Control, is set up in the hospitals and when necessary in the counties outside of the hospital. The Board consists of a lawyer who acts as chairman, a physician usually a psychiatrist and a woman generally a housewife. The motif of the law states that ideally one of the men should have some practical knowledge of vocational affairs, trade life and job opportunities. This Board exercises control over all private homes and nursing homes having mental patients, carrying out periodic inspections and making necessary recommendations. The Board gives a special character to the efforts of the community to preserve the initiative and the rights of the patients. The Board considers all admissions and discharges. The housewife stresses the creation of a wholesome home atmosphere as an essential for the adjustment of the patient to hospitalization or to the home outside his own home. The lawyer clarifies legal aspects and may present the request of the patient for discharge to the court in cases in which his request has been denied by the Control Board.

Dr. Lohne Knudsen, Director of The Psychiatric Division of The Health Services of Norway, states that of June 1961, there are 5000 patients in private care in Norway, 3000 in nursing homes and 8000 in overcrowded mental hospitals with 7000 authorized beds, and that the psychiatric services have 5 years in which to get sufficient money for 10,000 beds in mental hospitals. At present about one-third of the patients in private care are living with their own families. Patient care in private homes is confined mostly to country districts. It is becoming increasingly difficult to place these patients in the larger cities, especially Oslo.

FIVE PSYCHOTIC SIBLINGS

SVEN E. JENSEN, M.D.¹

A family heavily loaded with psychotic conditions has been thought of interest, although such a situation is not unique inasmuch as 5 siblings with psychotic episodes have been described by Osborn (10). Some of the pertinent psychodynamics will be described in discussing the possible etiology.

The family were farmers of German origin and Roman Catholic denomination. They came to Canada from the U. S. A. in 1919. The 7 children aged 25 to 37 were all born in Canada. They were full siblings and were all seen by the author when the 2 healthy siblings consulted me with an understandable concern about their prognoses.

The father, now in his early 60s, has played the role of a patriarch in the family, deciding what everyone would do, how and when it had to be done. About 10 or 12 years ago, the father was operated on for appendicitis. After that he was unable to work for 5 years, and restricted his activities to directing the farm work and family life from a chair. Only for the past 5 to 7 years has he been able to resume work but not on a very large scale.

The mother is rather obese. She had phlebitis after her third child, and after that she remained ailing and underwent several operations. She had the burden of bringing up the children until they were able to work. In doing so she was quite permissive. The children were considered as easy to bring up, but not much initiative was left to them. The socialization of the family appears to have been very poor all along, the father being conscious of his inability to speak English. He was very ill at ease in trying to define ownership of the family property. When one son (UR) married 6 or 7 years ago, the father bought a half-section of land, gave one quarter to his son and kept the remainder for himself, hoping that his son would be able to buy it in a few years. The quarter given to the son has no

buildings and his family live on the quarter belonging to the father. The son sees small prospect of being able to buy the quarter-section with buildings.

In the family setup the peculiarity should also be noted that the 3 girls and one son (AR) are all married into the same family, to 4 siblings. These are ambitious farmers, who have had their own difficulties, but apparently have been able to settle their problems successfully.

Case History—The Five Patients :

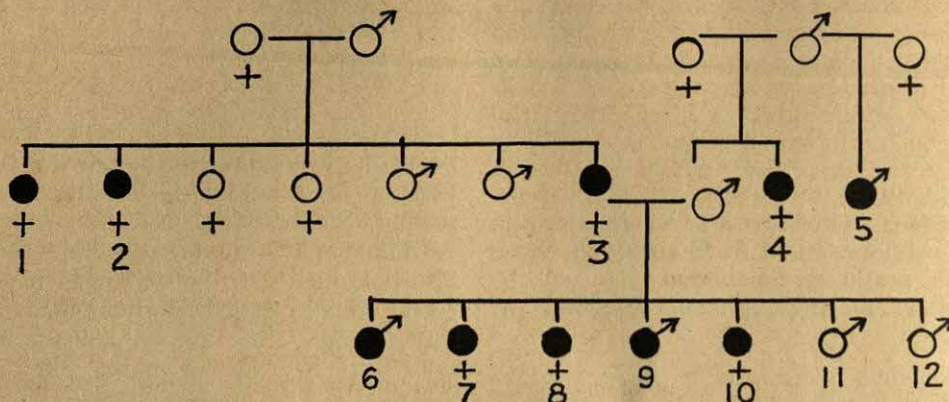

1. L.S. The third oldest of the children suffered from Sydenham's chorea at the age of 5 and had numerous relapses. Consequently she never attended regular school, and the mother states that she was advised by her physician always to give in to L.S.'s wishes lest she would cause more "nervous relapses." This caused a difference in the mother's attitude to her and to the rest of the children, the reason for which was never explained to them and which they all experienced as most frustrating and upsetting.

L.S. experienced her menarche at the age of 13, and in contrast to her sisters she never suffered from dysmenorrhea, but she says that although she went out with "lots of men" she never felt confident in their company. She went with her husband for about 1½ years before they married, but had known him most of her life.

She was first seen at the age of 26 when she was admitted to hospital because of depression of gradual onset, restlessness and feelings of inadequacy and guilt in connection with the birth of her second son 2 months previous. She had made a vague attempt at suicide 2 days prior to admission.

She was fully oriented and with intact memory although the powers of concentration were somewhat limited. She cried in an explosive way unrelated to the conversation and complained of hallucinations in the nature of voices calling her name. She felt that everybody was talking about her. The husband had been unaware of any changes in her personality up to 4 days prior to admission, but the patient later recalled that she had felt miserable for weeks and had been hallucinating when the baby was born. The last days before admission she had appeared bewildered and without peace of mind. The patient received 2 ECTs with good

12. Has asthma, is allergic to house dust.

symptomatic improvement; her vagueness and confusion cleared although she still complained of hallucinations and delusions. She soon became anxious to go home and left within 2 weeks of her admission. When seen 4 months later, she appeared dull and changed in personality, but she had no hallucinations and in the 2 years since hospitalization she has not required further psychiatric treatment.

2. U.R. This 29-year-old married brother sustained a back injury in the winter of 1955-56 and on July 15, 1956 he was admitted to the local hospital for traction therapy of his disc-syndrome. After one week in hospital, the patient suddenly developed a pain over his heart and said that he heard church bells and doves and felt that this was his calling to be a priest. He took the crucifix off the wall and held it against his chest praying the rosary repeatedly. The next morning he was found to say the rosary continually and he was at this time started on Largactil. However, this seemed to have little effect and one morning shortly after he was found wandering out of the hospital praying. He was, however, satisfied when given a Bible and for the rest of the day he read the Bible to the children. At this time, he developed a herpes zoster on the right side of his chest.

Although he appeared to be settling down in the following days, his mind was still wandering, and he expressed concern about having had sexual intercourse with his wife who was

then 7 months pregnant. At this time, he was transferred to the psychiatric clinic where he was found to be disoriented and confused, revealing hallucinations and stating that he felt depressed because God was not with him.

He was treated with ECT and in the following weeks improved so well that he was referred to the neurosurgical ward for operative treatment of his disc-syndrome. He again became psychotic, this time with hallucinations of taste and smell which made him think that his food was poisoned. He was readmitted to the psychiatric unit and once more had ECT with rapid improvement and about 2 months after his first admission, a disc operation was done successfully.

When seen a year later, he appeared well but stated that he still found it hard to meet people and indeed found it difficult to decide to come back for the follow-up interview, but his wife, wanting a trip to the city, had pushed him.

He was again admitted for a short period in 1960.

3. R.S., aged 30, the next in order of the siblings, had a grade VII education. She had then left school in order to work at home, but had been careless about this work although she was now perfectionistic in her own home. She used to side with her father in the family disagreements although she explains that he was strict and that she was scared of him.

She experienced menarche at the age of 13,

and this shocked her so that she cried. She could not believe that it was normal and thought that she had injured herself.

She married at the age of 24 after 2 years courtship. Her husband is 2 years older than she. She has proven frigid in marriage. This sister experienced her psychotic episode in October 1955 after the hired girl had left and she suddenly felt helpless left alone with a 3-week-old baby. The children got on her nerves and she would scream at them.

She suffered from insomnia, irritability and excessive worry and also complained of a group of fears, mostly generalized or in the nature of a fear of "going out of my mind." She was quite conscious of the family pattern of *post partum* illness.

This patient responded fairly well to a few psychotherapeutic interviews and she was never hospitalized. A follow-up in January 1957 found her to be in satisfactory mental health. "She seems to be talking all the time. She is just babbling about everything. I guess she was always that way," commented her brother U.R.

4. Y.S., the second youngest of the children, is said to have been the least shy of them all—quite talkative and very popular at dances. She was 26 years old when first seen for psychiatric treatment. She had been married for 7 years to a husband 6 years older than she, and had 4 children, the oldest 5 years, the youngest newborn.

About her childhood, she explained that she always felt lonely. She could never laugh with others, and she remembers being spanked by her mother for disobeying at the age of 10. She has resented her sister L.S. for always getting her own way, since she, as the other siblings, had not been told the reason for this.

Her menarche occurred at the age of 13, and the menstruations have been associated with dysmenorrhea.

She presented herself with the complaints of poor sleep, crying spells, restlessness and confusion. She was irritable towards her husband, who could not understand her and she thought that she was not a fit mother to her kids. She wondered during the initial interview, "Why am I not like other people?" She complained of a depressed mood, feelings of people poking fun at her, talking about her and leaving her with the feeling that she cannot do anything right. She was sleeping poorly. This patient was treated with a short course of psychotherapy on an outpatient basis only.

5. R.R. was the 25-year-old single "little brother." He was said always to have been shy and never a good mixer (and the father

at this point explained that he himself had been very shy when he was about the age of his son. This was at the time he came to Canada and did not speak English. He did not talk to other people unless they addressed him and even then it was painful to him to have to answer.) The mother stated that for the past year she had found her son more distant than usual. When talked to, there were times he would not answer and he seemed too much absorbed in his thoughts. Usually he would be slow in giving an answer, but would finally do so.

Prior to admission, he had been looking feverish for a couple of days, and had complained of pains in the stomach and a poor appetite for a couple of weeks. Mental disturbance was first noted when on the night before admission he woke up the parents by coming into their room in a very upset and confused condition and explained something about a fire going on and wanting to see a priest right away. On admission he was in the condition of catatonic stupor. Most of the time he would stare right ahead without answering questions or answering them slowly after a long delay. He was disorientated as to time, place and person, and appeared very anxious and fearful. He was apparently hallucinated on several occasions, speaking about bugs and snakes, and stating that he was in hell. He was given a series of 11 ECTs, in the beginning on a daily rate and later, 3 times a week. On this therapy, he soon cleared up and became rational, oriented and quite pleasant in a rather shy and timid way, socializing mainly with his brother who at this time was still in the hospital. As a matter of fact, the parents first thought that R.R.'s condition had been brought on by seeing U.R. psychotic in the local hospital, but in their usual inconsistent way they later decided that it was caused by religious difficulties in connection with a mission in the parish.

When discharged in September 1956 he showed no psychotic symptoms, but was withdrawn and seclusive, stating that he had no difficulties now and that it was no use speaking about personal matters, that they were not important.

This patient was admitted again in 1959 at which time the psychosis was considered precipitated by the death of a close friend. He improved on ECT and Stelazine but had to be admitted again in 1960.

DISCUSSION

This family then presents a great number number of psychotic episodes in 2 genera-

tions (since the family immigrated at that time, it has not been possible to trace the family history further back). Many of these have occurred in women after childbirth. All the conditions occurring in the second generation have been diagnosed as schizophrenia or schizophrenic episodes. The diagnoses of the conditions in the first generation are unknown. However, without going into details about the differential diagnostic criteria for schizophrenia, it should be noted that the term schizophrenia here is used in the rather broad sense in which it is commonly used on this continent. At the present state of our knowledge, it might prove more useful to refer to these conditions simply as psychotic episodes.

The family setup could be discussed in the light of what has in later years been described as schizophrenogenic, although this term is neither well defined nor well established. True, the concept of the schizophrenogenic environment usually considers that the mother is the pathogenic figure (5), but this is by no means generally agreed upon (7). Many authors, however, have questioned the hypothesis of a schizophrenic environment. Thus Langfeldt (6) "thinks it is wise to state merely that a mentally healthy and socially satisfactory environment probably tends to prevent the development of a schizophrenic process, while unsatisfactory factors may precipitate such a process." Jackson, *et al.* (4), have formulated the problem of how much the observer's bias in favor of his patient influences his picture of the parent or parents in these strictly subjective studies; and finally some authors, *e.g.*, Neilsen (9), have been unable to find any common characteristics in the attitudes of the parents.

Other authors with Rank (11) have been unable to exclude a hereditary influence since this influence merely predisposes the individual for this type of reaction pattern, and since as pointed out by Hendrickson (2) some of the descriptions of the parents given in the studies of the schizophrenic's environment suggest well compensated adult schizophrenias. One cannot but agree with the latter argument when one reads the following description of 12 fathers (7):

Nine showed notable defects in reality test-

ing that affected the family life markedly and perhaps influenced the mental disturbances of the children. Of these 9, at least 4 were paranoid both in regard to suspiciousness and in their type of thinking with which they expected their family to agree. Another was probably psychotic, but in an ill-defined way. One father was unable to modify his way of living and his opinion of himself after unsurmountable business reverses. He failed to recognize that he was a serious drain upon the family resources and an abysmal failure, rather than an important or great man, as he continued to convey to the world. Two or three, unable to recognize or counteract their wives' fantastic ideas, abetted them as if living in a *folie à deux*, producing an unrealistic environment in the home.

It would appear that those of the above fathers who were not overtly psychotic exhibited what has been referred to by Arieti (1) as an "externalized psychosis" by which Arieti means that the patient succeeds in changing and manipulating his environment according to his bizarre wishes, and therefore has no need to develop overt psychotic symptoms. Through his manipulations, he is able to organize a little world where everybody else has to respect his eccentric wishes. Arieti points out that these persons often create situations which will precipitate or engender psychoses in other people.

The father of the family here discussed seems himself to have exhibited an "externalized psychosis"—at least the way he rules his little kingdom from his chair, tolerating no contradictions, personal opinions or interference from outside; and distributing farmland, *etc.*, in a confused manner would suggest this.

It would however appear that this or other "psychodynamic interpretations" in no way rules out or contradicts a hereditary or even a biochemical "explanation." Certainly the genetic factor at best is only a predisposing, not a causal one, as pointed out by Huxley (3), one and the same genetic outfit will give different effects in different environments. In other words an individual possessing the genes characteristic of schizophrenia may develop a schizophrenic condition in one environment and not in another. Obviously such a theory must stimulate us to investigate further which environmental factors may be disposing for

schizophrenia and which may be prophylactic. Such a combined genetic-environmental approach is not necessarily opposed to the school that considers a somatic etiology to schizophrenia. In the same way as it is generally agreed that somatic conditions such as peptic ulcer, *etc.*, can develop on a psychic basis, it might well be that emotional factors could cause alterations in the metabolism which in turn "caused" or precipitated the psychotic symptoms. In the light of modern findings this would not appear to be too theoretical a concept. Certainly with increased emphasis on body mind relationship it should be understood that this relationship does not work one way only, but is reversible.

SUMMARY

A family is presented in which 5 of 7 siblings and 10 of 17 members of the last 2 generations have had psychotic episodes. At least 5 members have experienced their mental illness in connection with childbirth, and 2 in connection with back injury. It

is suggested that our interpretation does not rule out a hereditary or somatic concept.

CLINICAL NOTES

(The Clinical Notes report the findings of the authors and do not necessarily represent the opinions of the Journal.)

CHARACTERISTICS OF CHANGE OF SCHIZOPHRENIC PATIENTS DURING TREATMENT

DONALD R. GORHAM, Ph.D.,¹ AND BARBARA J. BETZ, M.D.²

A Nurses Behavior Chart (Figure 1) which contains 44 items of psychiatric behavior has been used at the Henry Phipps Psychiatric Clinic of the Johns Hopkins Hospital since 1914(1). It is a graphic chart on which the nurses' daily observations of the patient are recorded, supplemented by descriptive notes of the patient's behavior. It is not designed for recording motivations or subtle interpretations of behavior. There exist subtle differences in behavior which are of much psychiatric importance, but which are not conveniently observed and described in uniform ways by different nurses. The items on the chart are not expected to give a complete record—they are samples of behavior which can be definitely observed by the nurse, and were selected as suitable for marking on the chart. This chart has proved to be a sensitive indicator of changes in the patient's condition both in favorable and unfavorable directions. Such data made possible a study to determine the patients' symptoms which change during the course of treatment.

In former studies utilizing the Nurses Behavior Chart and the Strong Vocational Interest Blank, Whitehorn and Betz(5, 6) have demonstrated differential psychotherapeutic treatment effects according to physician's personality type. Gorham and Overall (2, 3, 4) have found that change-sensitive symptoms may be isolated by factor analyzing the items of psychiatric rating scales. In this study, the dimensions of change found by factor analyzing the items of the

Nurses Behavior Chart will be reported.

Behavior ratings on a sample of 100 schizophrenic patients were averaged for each of the 44 items for the first and last weeks of hospitalization. This sample was drawn at random from 256 available cases. It consisted of 32 males and 68 females ranging in age from 12 to 62. The ratings were averaged over the 7-day period to increase the reliability of the measures and to emphasize the more enduring and characteristic dimensions of patient symptomatology. It had the additional effect of reducing negative correlations between antagonistic symptoms and behaviors since day to day fluctuations differed from patient to patient.

The mean ratings on the 44 measures, based on the initial week of hospitalization, were intercorrelated and a principal axis factor analysis and normalized varimax rotation were accomplished by digital computer. Since the factor analysis and rotation were made without consideration of the nature of the variables involved, a high degree of objectivity can be claimed for the results.

Table 1 shows the rank order of all items with a loading of more than .30 on each of the ten rotated factors. Loadings above .50 are indicated in the table. It is apparent that 8 of the 10 factors can be defined by a cluster of 2-4 items with very substantial loadings. The factors thus isolated may be described as follows: 1. Asocial acting out, 2. Motor retardation, 3. Psychotic deterioration, 4. Agitation, 5. Mental health (patient assets), 6. Unusual motor behavior, 7. Thought disturbance, 8. Depression, 9. Not definable as a meaningful symptom area, 10. Lack of initiative.

The extent to which the factors are use-

criterion of change. The criterion was the final psychiatric evaluation of the Clinic which assigned grades of improvement or unimprovement to each patient at the end of treatment. This judgment, made by the Chief Resident, with the approval of the Chief of the service, is based upon a decrease in clinical manifestations of illness, an increase in socially effective behavior in the hospital, evidence of patient's ability to get along with others and live in the

community as manifested in home visits, shopping trips, *etc.*, and evidence of changes in personal attitudes toward greater self-confidence and initiative, indicating progress in personal problem solving. For the purposes of this study, the patients were dichotomized into improved or unimproved (including no change) on both the criterion and the factor change-scores. The 2 x 2 chi squares between psychiatric evaluation of improvement and factor scores based on the Behavior Chart data are shown in Table 2.

TABLE 2

Validity of Factor Scores as Measures of Change
(Criterion : Phipps Clinic discharge evaluation)

FACTOR	X ²	P
1. Asocial acting out	7.70	.01
2. Motor retardation	5.19	.05
3. Psychotic deterioration	5.36	.05
4. Agitation	2.61	—
5. Mental health (assets)	7.36	.01
6. Unusual motor behavior	1.05	—
7. Thought disturbance	13.23	.001
8. Depression	13.84	.001
9. (Not interpretable)	5.14	.05
10. Lacking initiative	18.23	.001
Total pathology (excluding 5 and 9)	11.84	.001

It will be noticed that factors 1, 7, 8 and 10 indicate pathology in schizophrenic patients which is highly sensitive to change during treatment. Item 5 indicates certain patient assets which develop positively as pathological symptoms decrease. A combination of the four areas of pathology and one area of "health" should provide a highly reliable index of change associated with treatment. Such an index could be based on 14 items of behavior which can be observed and rated by the nursing service, *viz.*, combative, resistant, angry, delusions, hallucinations, suspicious, confused, sad, weeping, apprehensive, brooding, lack of initiative, cheerful and calm. Further studies are needed to validate these findings. If nurses' ratings on these items can produce a reliable and valid index of patient change, it has great potential usefulness both to augment and confirm clinical evaluation. In research studies such an index could be used where staff limitations preclude the use of clinical assessment teams.

SUMMARY

Forty-four items of a Nurses Behavior Chart used at the Phipps Psychiatric Clinic of Johns Hopkins Hospital were factor analyzed, based on a sample of 100 schizophrenic patients. Ten orthogonal factors which were extracted indicated the dimensions of schizophrenic illness. Five of these factors (based on 14 behavior items) provide an index of treatment change which is highly significant when compared with clinical judgment of improvement. The index has clinical and research potential.

THE USE OF A PHENOTHIAZINE COMPOUND IN THE REHABILITATION OF SCHIZOPHRENIC PATIENTS

HANS O. GERZ, M.D.¹

As part of our continuing investigation of the various phenothiazine derivatives in the rehabilitation of schizophrenic patients, we have studied the use of perphenazine² in 54 consecutive female psychotics, ages 18 to 56, admitted to our Admission Service for the first time or readmitted following a relapse. There were 26 cases of schizophrenia of the paranoid type, 11 of the catatonic, 13 of the chronic undifferentiated, 2 of the acute undifferentiated, and one each of the hebephrenic and simple types.

Perphenazine was given orally, 4 mg. t.i.d. the first day, 8 mg. t.i.d. the second, and 12 mg. t.i.d. from the third through the 21st day. When there was resistance to the ingestion of medication initially, perphenazine concentrate was given, mixed in beverages.

The more severely agitated and disturbed patients were also given 5 mg. of intramuscular perphenazine, p.r.n., during the first 10 days. Patients were evaluated by the author at the end of each week. If there was a definite response, treatment was continued for another week at the same dosage, or at 16 mg. to 24 mg. t.i.d. if it was felt that an increase in dosage would result in a better response.

At the end of the fourth week, patients were reevaluated by the author. Treatment was continued with 12 mg. t.i.d. during the fifth week and 8 mg. t.i.d. during the sixth and seventh weeks. At that time, maintenance dosage was established, based upon staff evaluation of the patient's overall response. At the end of 3 months, medication was discontinued where possible or the patient placed on a long term maintenance regimen of perphenazine, 8 mg. t.i.d., and trihexyphenidyl hydrochloride, 5 mg. t.i.d. If improvement was sufficient, patients were allowed to go on extended home visits, or were discharged and transferred to the outpatient clinic on this regimen. Hospital treatment lasted from 6 weeks to 4 months.

Before therapy, the patient's prognosis was recorded as "good," "guarded" or "poor," according to the duration of the disease, the number of previous relapses, and the overall status on admission. This prognosis was based on the results obtained with other phenothiazines in similar cases, and not on those seen in the prepsycho-pharmacologic era.

Results were recorded as "excellent" if there was complete disappearance of psychotic symptoms such as delusions and hallucinations, improvement or return of affect, and appreciation of having been ill; as "good" when there was complete disappearance of delusions and hallucinations, and

¹ Clinical Director, Connecticut Valley Hospital, Middletown, Conn.

² Trilafon, Schering.

appreciation of having been ill, but when blunting and flattening of affect persisted; as "fair" when there was complete disappearance of delusions and hallucinations, but no realization of having been ill and persistence of marked blunting of affect; and as "poor" when there was no significant change in the patient's status.

Response was excellent in 26 cases, good in 13 and fair in 6; there were 9 failures (see Table 1). Of the 34 cases with a poor

treatment with other phenothiazines, such as chlorpromazine, commented that they were able to tolerate perphenazine much better, because it did not cause sleepiness or drowsiness or that "dragged-out" feeling. Recreational and occupational therapists reported that patients on perphenazine remained alert and responsive, and participated more readily in occupational therapy.

Occasional blurred vision which usually disappeared spontaneously after several

TABLE 1
Results in 54 Patients Correlated with Diagnosis

CARPHENAZINE¹ IN THE TREATMENT OF CHRONIC SCHIZOPHRENICS

JOSEPH A. BARSA, M.D., AND JOHN C. SAUNDERS, M.D.²

Clinical experience has shown that tranquilizing drugs have two chief therapeutic actions: a sedative or calming action and an anti-psychotic (*i.e.*, anti-delusional and anti-hallucinatory) action. Different drugs possess these attributes in varying degrees. In our work with a large number of tranquilizers, we have noticed that the stronger the anti-psychotic effect the weaker is the sedative effect, and vice versa. Moreover, the greater the anti-psychotic action the greater is the incidence of extrapyramidal side-effects, such as, parkinsonism, akathisia and dystonia. At present the class of drugs with the greatest anti-psychotic action is the piperazine group of phenothiazine derivatives. Efforts have continued to find new drugs with potent anti-psychotic action and with less side-effects. It was with this aim that carphenazine (Proketazine), a phenothiazine derivative with a piperazine ring, was developed.

This study tested the effectiveness of carphenazine in the treatment of chronic schizophrenics. Fifty-four female patients between the ages of 25 and 71 were selected. They had been continuously hospitalized for 5 to 33 years, and had received a variety of psychotropic drugs for at least 3 years with slight or no improvement. During the last year 22 patients received levomepromazine (Nozinan), 18 trifluoperazine (Stelazine), 11 chlorpromazine (Thorazine), 2 prochlorperazine (Compazine) and 1 fluphenazine (Permitil, Prolixin). The patients remained untidy, seclusive, withdrawn, preoccupied, flat in affect, delusional and/or hallucinated.

All previous medication was discontinued, and the patients were placed on carphenazine at a starting dose of 12.5 mg. q.i.d. The dosage was gradually increased until either satisfactory therapeutic results were achieved or side-effects appeared. The high-

est dose reached was 125 mg. q.i.d., but the majority of patients received 75 to 100 mg. q.i.d. The drug was continued for 3 to 7 months. At the end of this period one patient was evaluated as markedly improved, *i.e.*, in remission, free of delusions and hallucinations, and ready for release from the hospital; 3 were moderately improved, *i.e.*, although still delusional and/or hallucinated, they were now more alert, more interested in their environment, more sociable, and more active in the hospital program; 13 were slightly improved, 21 unimproved, and 16 were considered worse. The latter were more tense, irritable, hostile, and were reacting more overtly to their delusions and hallucinations.

Side-effects were similar to those previously encountered with other members of the piperazine group of phenothiazine derivatives, except that the carphenazine side-effects were on the whole less severe and more easily controlled. Two patients experienced generalized tremulousness, 20 manifested akathisia, and 17 patients showed the parkinsonian signs of rigidity, tremor and increased salivation. These side-effects responded partially or completely to benztropine methanesulfonate (Cogentin). Blood and urine examinations revealed no abnormalities during the course of this study.

In summary, carphenazine shows chiefly an anti-psychotic (*i.e.*, anti-delusional and anti-hallucinatory) effect and very little of a sedative effect. Moreover, even in its anti-psychotic action it is one of the less potent piperazine-type phenothiazine derivatives, slightly less potent than prochlorperazine. However, as would be expected, the extrapyramidal side-effects of carphenazine are less severe and more easily controlled. Thus, carphenazine is most useful in cases where little sedation is required, where delusions and hallucinations are not firmly entrenched, or where the stronger anti-psychotic drugs produce excessive side-effects.

¹ Carphenazine was supplied by Wyeth Laboratories as Proketazine.

² Rockland State Hospital, Orangeburg, N. Y.

months prior to this study, and only 4 patients had received any medication in the previous 6 months. Lumbar puncture was performed and the fluid examined for protein content by the sulfosalicylic method. Lange gold curves were carried out according to the modification of this procedure described by Lange and Harris (4, 5).

All patients were then started on triiodothyronine (T_3) (Cytomel),³ 25 mcgm. per day increasing every 2 weeks by 25 mcgm., until a level of 100 mcgm. per day was reached, at which level they were maintained for 45 days. Repeat lumbar puncture was performed at this time and the gold curve and protein content were examined.

RESULTS

Table I shows the detailed results of the cerebrospinal fluid protein and gold curves (proteins were obtained on 26 patients and gold curves on 27 patients). The mean protein level, pre- T_3 , was 39 mgm.% (upper limit of normality 40 mgm.%) and that after the course of T_3 , 30 mgm.% ($p < 0.05$). Pre- T_3 , 10 patients had a value above 40 mgm.%; post- T_3 , only 4 patients had a level above 40 mgm.%.

Of the 27 gold curves, 8 were reported as normal; 8 slightly abnormal; and 11 markedly abnormal, pre- T_3 . Following the course of T_3 , 13 were normal; 10 slightly abnormal; and only 4 markedly abnormal.

DISCUSSION

Bruetsch in his large series of schizophrenics found a mean protein level in spinal fluid of 74 mgm.%, which is considerably higher than the level found in this series. On the other hand, the small sample re-

ported here certainly shows a higher percentage of elevated protein than in his series. This discrepancy may be related to age or chronicity of illness in these patients. The difference in results following the course of T_3 is much less, but one wonders whether a similar effect might not have been apparent in Bruetsch's series. A possible relationship of these findings to hypothyroidism in chronic schizophrenics has been reported on elsewhere (6) and will not be discussed here. The writers wish merely to bring these findings to notice. It is, however, their opinion that the findings are related to hypometabolism in chronic institutionalized patients.

SUMMARY

1. In a group of 27 chronic schizophrenics chosen randomly, abnormalities in the cerebrospinal fluid protein and gold curve were noted.
2. A statistically significant normalizing effect on these indices occurred when the patients were placed on tri-iodothyronine.
3. The relationship of the findings to thyroid function has been discussed elsewhere. Decreased metabolism is presumed to be a relating factor.
4. Further work in this area seems indicated.

A PRELIMINARY STUDY OF AMITRIPTYLINE IN THE TREATMENT OF DEPRESSION

THOMAS FAHY, M.B., B.Ch.¹

Twenty depressed patients, 11 men and 9 women, attending a psychiatric clinic

were selected as suitable for antidepressant drug therapy. All cases were of moderate severity; the average age was 43 years. Fourteen cases had endogenous depression, 6 were neurotic depressives. The average

¹ The Royal Victoria Infirmary, Dept. of Psychological Medicine, Newcastle upon Tyne 1, Durham, England.

duration of illness before treatment was 7 months; four cases had had prior drug treatment for their present illness, but not amitriptyline (Tryptizol²). Patients received 25 mgms. of the drug for 1 week, and 50 mgms. t.d.s. for 5 weeks, after which observations were discontinued. All patients received a small nightly dose of barbiturate. Side-effects were few, none were serious, and they tended to disappear during the second and third week of therapy; commonest were dry mouth (80%) and drowsiness (40%). Dry mouth, dizziness and sweating tended to persist. Sudden hypomania necessitating withdrawal of the drug was seen in 1 case. Three patients reported panic attacks at night during the second and third week. Patients were assessed at weekly intervals, results being shown in the following table:

² Kindly supplied by Messrs. Merck, Sharp and Dohme Ltd.

	ENDOGENOUS		REACTIVE
Recovered (i.e., asymptomatic)	9	6	3
No change or worse	9	6	3
Defaulted (because of anxiety)	2	1	1

Cases who responded to amitriptyline showed improvement which began during the first week and was clear cut in the second. The phenomenon of delayed response was not observed. The drug showed no definite anti-anxiety effects. Cases which failed to respond to amitriptyline after 4 weeks were subsequently given EST with good results in endogenous cases.

Amitriptyline appears to be an effective antidepressant in cases of moderately severe depression with good previous personality and minimal reactive features. The results of this pilot investigation are sufficiently encouraging to warrant full scale controlled clinical trials.

THIRD EVALUATION OF HALOPERIDOL

HERMAN C. B. DENBER, M.D., DANIELLE FLORIO, M.D., AND
PAUL RAJOTTE, M.D.¹

We have previously reported mediocre results with Haloperidol(1), contrary to rather enthusiastic observations in different European centers(2). A second study was carried out at this hospital,² using the product shipped directly from the Belgian pharmaceutical laboratory,³ and then repeated in Liège with a matched sample, using similar criteria for clinical change. The latter results this time were almost identical to those in New York and have been reported in greater detail elsewhere (3). While the dose range was still markedly inferior to the New York levels, the side effects were greater in Liège.

The present report deals with a *third* uncontrolled trial with Haloperidol, combined with an antiparkinson agent (SC-

12333),⁴ which was supposed to synergize the action of the former. The study was carried out in the Research Division of the Manhattan State Hospital, which has 55 acute and chronic female psychotic patients and operates as a therapeutic community with an open door.

Twenty-one patients, ranging in age from 19 to 50 years, received the drugs; the majority were in the 20-39 year group. Seventeen were schizophrenic. The duration of treatment was: to 15 days—7; 16-29 days—5; 30-39 days—2; 50-69 days—7. The final daily dose of Haloperidol was: 5-60 mg.—14 patients; 90-150 mg.—3 patients; 200 mg.—4 patients. SC-12333 was given in doses ranging from 30-300 mg. daily. An extrapyramidal reaction (13 patients), drowsiness (9 patients), and dizzi-

⁴ 1-(4-chlorophenyl) cyclohexyl 2-diethylaminoethyl ether HCL. Both drugs were made available through the courtesy of Dr. Thomas H. Hayes, G. D. Searle & Co., Chicago, Illinois.

ness (5 patients) were the major side reactions.

The results were: much improved—3; improved—7; unchanged—9; worse—2. For the most part, patients with a good prognosis (short hospitalization before treatment) were in the first two categories. The inverse was true for those unchanged and worse; they had longer hospital stays and/or several readmissions.

DISCUSSION

The SC-12333 did not influence either the clinical state or the extrapyramidal reaction. One patient developed a confusional state with severe anxiety, hallucinations, marked tremor and fever (100.4° F.), while receiving 200 mg. daily of Haloperidol, and 90 mg. of SC-12333. The drugs were stopped immediately and the syndrome regressed within 48 hours. This type of reaction requires immediate cessation of medication, for it may be fatal.

The clinical results were not remarkable and could not corroborate other European investigations(4). The present equivocal

findings were similar to our previous studies. The importance of well-defined criteria for clinical change is illustrated by results of the second trial; adoption of our criteria during phase two of the study in Liège gave comparable results.

CONCLUSION

After three clinical trials, we have been unable to confirm the reported "superior neuroleptic" potential of Haloperidol. A genetic mechanism has been postulated to explain the differences, and this is being explored further(5).

TRANSIENT PSYCHOTIC REACTIONS DURING TRAVEL

DON E. FLINN, Lt. Col., USAF (MC)¹

An interesting case of a psychotic disorder which developed during a 48-hour train ride has recently been reported by Singh(1). It may be worth pointing out that similar cases have been observed in the military population, where long periods of travel are not uncommon. At one Air Force hospital over a 3-year period, 22 cases of this "travel syndrome" were reported by Gaarder, Smith and the writer (2), and other similar cases have been seen by Army and Navy psychiatrists(3, 4). The events preceding the psychosis and the symptoms were strikingly uniform in these cases. Typically the individual had been traveling alone for several days on a bus, train or plane, and often there was a history of considerable alcohol intake prior to departure. During the trip he had

eaten irregularly, had a minimal fluid intake, and often developed insomnia. The psychiatric symptoms usually occurred explosively after two or three days of travel. Hallucinations, delusions and ideas of reference were present in each of the 22 reported cases. The individual's fear and his pleas for protection from some delusional threat resulted in his hospitalization, often through the hands of the police. Most of the patients had a clear sensorium, though 5, who were very heavy drinkers, showed disorientation, confusion, tremor and fever consistent with delirium tremens. However, even in these the hallucinations were often auditory rather than visual and the delusional ideas were fairly well organized and coherent. Thirteen other patients were moderate to heavy drinkers, while in 4 there was no history of alcohol intake. Treatment consisted of sedation, correction of fluid deficiencies, and adequate nutri-

¹ School of Aerospace Medicine, Brooks Air Force Base, Texas.

tion; one-fourth of the patients received small doses of chlorpromazine hydrochloride. Most patients were entirely asymptomatic within one week. In the 4 with no history of alcohol intake, recovery was not quite so prompt; while the overt psychotic symptoms had disappeared in all within 3 weeks, 2 had only partial insight into the delusional nature of their experiences.

It seemed likely that both psychologic and physiologic factors had combined in these patients to produce the transient psychotic condition. In those cases resembling delirium tremens, physiologic factors related to alcohol withdrawal seemed most important while at the other extreme were cases in which the psychologic stress of travel seemed capable of precipitating the psychotic disorder. Many of the cases between these extremes resembled alcoholic hallucinosis, although in one patient the threats were homosexual in nature. More common were hallucinations threatening bodily harm, or accusations as to various crimes, communist activities, security violations or heterosexual activities.

As Singh pointed out, there have been many reports that experimental isolation can produce cognitive and perceptual distortions(5-7). These take the form of impaired concentration, vivid visual imagery, auditory hallucinations, and changes in body image. Typically the perceptual illusions are brief, with the subject having insight into their unreality; however, a reaction of several hours duration characterized by hallucinations and ideas of reference without insight has been described (8). While men traveling are not "isolated" in the ordinary sense of the word, a trip of

several days duration among strangers, with unaccustomed surroundings, inactivity, monotony and absence of the usual social relationships may promote fantasy and impair reality contact in an otherwise predisposed individual. These reactions resemble the transient psychotic disorders observed in post-operative cataract patients who have both eyes bandaged(9), in poliomyelitis patients being treated in a tank-type respirator(10), and in other medical and surgical conditions reviewed by Leiderman, *et al.* (11). Common to all these disorders is the rapid resolution of symptoms when normal perceptual contact with the environment is re-established.

LIFE CYCLES IN PATIENTS WITH MANIC-DEPRESSIVE PSYCHOSIS

JANE E. OLTMAN, M.D., AND SAMUEL FRIEDMAN, M.D.¹

This report is one phase of an extensive study which we are conducting on manic-depressive psychosis. It encompasses data extending over many years; in fact, the first hospitalization of some of our subjects oc-

curred in the 19th century. It should be noted that the majority of these patients did not receive specific therapy during their multiple hospitalizations; accordingly, the data may be helpful in evaluating the long-range influence of various types of treatment.

¹ Fairfield State Hospital, Newtown, Connecticut.

This portion of the investigation includes 187 patients—84 males and 103 females—who completed their life cycles by December 1961. Their ages at first hospitalization and at death are summarized in Table 1.

TABLE 1

AGE	A. AGE AT 1ST HOSP.		B. AGE AT DEATH	
	M	F	M	F
Under 21	2	1	0	0
21-30	10	16	1	0
31-40	17	18	2	5
41-50	11	19	7	9
51-60	19	22	12	16
61-70	16	19	25	26
71-80	7	7	29	38
81-90	0	0	8	9
Unknown	2	1	0	0

In 9 men and 20 women, there was a history of an earlier, well-defined cyclothymic episode prior to the first known hospitalization. This does not affect the conclusion that manic-depressive psychosis is essentially a disorder of mid to late adult life. The data in column B would indicate that longevity is not greatly influenced by the illness. The average age at death was 66 for men and 65 for women. The latter figure may represent a slight decrease in expected longevity in females. We are unable to explain why such a high fraction (65%) of Pollock's² large series of manic-depressive patients died before the age of 50.

Causes of death did not appear to exhibit any significant trend except for one factor, suicide. This accounted for 13 deaths (7%)—8 men and 5 women. Six of these occurred in the hospital or its grounds.

The individual number of hospitalizations experienced by these individuals during their complete life cycles is indicated in Table 2.

The total number of hospitalizations was 561, with an average of 2.5 in men and 3.4 in women. Multiple hospitalizations were not quite as frequent as one might have expected. They were, however, definitely greater than in Pollock's report, in which

TABLE 2

NO. OF HOSPITALIZATIONS	M	F	TOTAL	% OF GROUP
1	24	16	40	21%
2	35	32	67	36
3-4	12	32	44	24
5-6	10	13	23	12
7-9	3	7	10	5
10 or more	0	3	3	2

58% of subjects experienced only one hospitalization. The influence in this area of long, protracted hospitalizations in past years is great. There were more hospitalizations in those whose illness began relatively early. Thus, females whose first hospitalization occurred before 50 experienced an average of 4.1 hospitalizations; males, 2.9. Conversely, early death decreased the number of hospitalizations. Women who died before the age of 50 had an average of 2.7 hospitalizations; men, 1.8.

Some of the reasons for single hospitalizations were as follows. Among the men, 5 committed suicide; 5 were over 70 at the time of first hospitalization; 7 experienced only a single, protracted hospitalization (100 months or longer) from the time of admission until death; and 1 died during EST—a total of 18 (75% of those with single hospitalization). Among females, the corresponding figures were: 2 suicides; 5 over 70 at first hospitalization; and 2 with single, protracted hospitalization—a total of 9 (57%).

The total amount of time which these individuals spent in hospitals is summarized in Table 3.

TABLE 3

TOTAL TIME IN HOSPITALS	M	F	TOTAL	% OF GROUP
1-24 months	32	42	74	40%
25-50 months	9	20	29	16
51-100 months	8	16	24	13
101-200 months	25	13	38	20
201-300 months	4	8	12	6
301-400 months	5	2	7	4
401-500 months	1	2	3	2

Thus, 60 (32%) spent more than 100 months in hospitals—obviously a substantial segment of their adult lives. The average

² Pollock, H. M.: *Am. J. Psychiat.*, 88: 567, 1931.

total time was 100 months for men and 70 months for women. Another expression of these data is as follows. From first hospitalization until death, men spent 38% of their years in hospitals; women, 34%.

The duration of individual, "untreated," episodes in state hospitals (episodes in private hospitals were excluded from this analysis for obvious reasons), irrespective of their ordinal number, is indicated in Table 4.

factors may be influential in this area. The reduction in protracted hospitalizations in recent years may be due not merely to administration of specific therapies, but also to changing administrative and professional concepts, altered attitudes in the family circle and in the community, greater availability of extramural care, *etc.*

It is apparent that difficulties may arise in the comparative analysis and interpretation of statistics of recent date and those

Table 4
Duration of 402 "untreated" episodes in state hospitals

DURATION	DEPRESSED		MANIC		OTHERS	
	M	F	M	F	M	F
under 12 months	35	78	39	83	6	11
12-24 months	5	9	7	11	1	2
25-50 months	8	13	11	8	2	3
51-100 months	5	2	8	5	1	3
100+ months	8	3	14	12	3	6
	61	105	79	119	13	25
Over 1 year — No.	26	27	40	36	7	14
— %	43%	26%	51%	30%	54%	56%

Thus, 150 episodes (37%) were longer than 1 year, and 46 (11%) longer than 100 months. There were 36 patients in the group of 187 (20%) who experienced individual hospitalizations, enduring 10 years or more. It is evident also that protracted hospitalizations were somewhat more common in men than in women, and more frequent in manic and circular episodes than in depressive attacks. A fairly characteristic course of the disease was one in which 2 or 3 earlier, relatively brief hospitalizations were succeeded by a lengthy, terminal one.

It should be noted, of course, that several

of the past. As an example: a depressed patient may have had 4 admissions and discharges during the 1950-60 decade, each illness being successfully treated with EST or antidepressant drugs. What will be the basis of comparison in a broad, statistical survey, of these 4 admissions and the implicit 3 recurrences, with a case of a single, protracted hospitalization in an earlier decade? How is the influence of the previously noted incalculable factors to be measured? It is obvious that multifactorial, long-term, carefully appraised analyses are necessary for the overall evaluation of specific therapies in psychiatry.

AN ALTERNATE METHOD OF EXTERNAL CARDIAC MASSAGE

STEPHEN J. BARRETT, M.D.¹

An elderly woman with mild organic brain deficit was hospitalized for treatment of depression. Following her first ECT with

Pentothal and Anectine, she was apneic. Although artificial ventilation of the lungs appeared to be adequate, the patient became deeply cyanotic over a period of 3 minutes. Her heartbeat at that time was

¹ Chief, Neuropsychiatric Clinic, USAF Hospital Scott, Scott Air Force Base, Illinois.

not audible. It was observed that the patient had a very thin abdominal wall and "cardiac massage" was attempted by the physician pushing his hand well up under the left lower costal margin and rhythmically pushing and squeezing. After a few such maneuvers the patient's heartbeat was restored, and she eventually recovered with no signs of increased organic impairment. It was thought in retrospect that her cardiac arrest was the cause of her respiratory failure (and not vice versa), but this could not be proven.

In a recent series² of 46 patients who received external cardiac massage, autopsy

findings revealed that 15 (33%) had sustained rib fractures and six (13%) had had marrow emboli to the lungs or heart. The authors suggest that with more careful application of the sternal pressure technique, the number of such complications may be reduced considerably. This case is reported to suggest an alternate simple method of external cardiac resuscitation. Applicable to people with weak abdominal walls, it may prove safer and just as effective as chest pressure method.

² Baringer, J. R., *et al.*: New Engl. J. Med., 265: 62, July 1961.

CASE REPORTS

CARDIAC ARREST AFTER ECT

SUNE NYSTROEM, M.L.¹

In the May 1961 issue of this Journal Arneson and Butler(1) suggest utilizing the method of closed chest cardiac massage in patients with cardiac arrest following ECT. It might be of value to relate that this technique was used in June at the University Hospital in Lund.

The patient was a woman of 62, hysteroid personality, with a protracted global depression of moderate depth, reactively provoked. Physical examination and electrocardiogram were normal. The blood pressure was 200/90, the patient was tense. The body length was 164 cm. (5'6") and the weight only 47 kg. (103.4 lbs.) but there was no emaciation. Except for levomepromazine (Nozinan) 25 mg. in the evenings, no drug treatment was given. The actual complication took place at the first convulsive treatment. Two hundred-fifty mg. Evipan-Natrium was given i.v., followed by 25 mg. succinyl-choline (Midarine). The convulsion was normal. During the subsequent oxygen administration the patient turned pale. No pulse could be felt, no blood pressure measured and no heart sounds could be detected by auscultation. Closed chest cardiac massage was started, and after some minutes blood pressure could be measured, 115/80, and heart sounds were heard. The total time of arrest was rated to have been 3-4 minutes. No signs of persistent cerebral or cardiac damage could be detected in the

examinations performed later.

It should be noted that at our department there has been no previous case of cardiac arrest and no death in connection with ECT; about 25,000 treatments have been given with the same technique since 1953.

From the clinical reports it seems as if heart massage after thoracotomy in connection with ECT often has not been given at all, *e.g.*, in none of the 9 fatal cases reported by Barker and Barker(2). When given it has often turned out unsatisfactorily, as in the cases reported by Arneson and Butler(1), and by Drake and Ebaugh (3). A possible explanation for these facts is the psychiatrists' lack of experience in surgical procedures. Therefore, if the closed methods with cumulating experience prove satisfactory, they might be a relatively greater advancement for psychiatric practice than for many somatic disciplines, where surgical interference is more easily achieved.

MOTHER'S MILK AND CHLORPROMAZINE

K. H. BLACKER, M.D., BELSON J. WEINSTEIN, M.D., AND
GEORGE L. ELLMAN, Ph.D.¹

The problem of dispensing drugs to nursing mothers arises in all medical specialties. The physician must be alert to the possibil-

ity of the infant's being affected by medications prescribed for the mother. This was the problem in prescribing chlorpromazine for a nursing psychotic woman. Although chlorpromazine has been widely used, the amount of the drug that may be secreted

¹ The Langley Porter Neuropsychiatric Institute, Dept. Mental Hygiene, University of California, School of Medicine, San Francisco.

in the milk and its effect on the nursing infant have not been clearly described. This paper is the report of our measurement of chlorpromazine in the blood and milk of a lactating woman.

Joan J., a 20-year-old, married woman, became psychotic immediately after the birth of her first child. The unexpected premarital pregnancy had necessitated a hasty marriage and exploded many of her expansive plans for the future. She was depressed and unhappy during the pregnancy, and immediately after an uncomplicated vaginal delivery became grandiose and manic. Four days later she entered Langley Porter Neuropsychiatric Institute.

On admission she had flight of ideas, loosened associations, inappropriate behavior, and hypomanic activity. Physical examination was normal. She was adamant in her desire to nurse her child; consequently the flow of milk was maintained by pumping the breasts every four hours. She was started on chlorpromazine and maintained on 1200 mg. daily. Within 10 days the patient had improved greatly.

During Joan's hospitalization her child was brought to her at scheduled intervals and she cared for and breast-fed the child without difficulty. The infant's growth, activity, and development during this period were normal. The patient was discharged 18 days after admission.

Procedure. The patient was given a single 1200 mg. dose of chlorpromazine (20 mg./kg.). A venous blood sample was obtained before the single dose, and at 30, 60, 90, and 180 minute intervals thereafter. Milk was expressed by a breast pump before, and also 60, 120, 180 minutes after chlorpromazine administration. The volume was recorded and the sample immediately refrigerated.

Chlorpromazine determinations on the milk and plasma were done by the method of Salzman and Brodie (1956) and final assays made on a recording spectrophotometer (Beckmen DK-1). The spectra of the final acid extracts were determined from 235-280 mμ to make certain that the absorbance determined at 252 mμ was due to chlorpromazine.

DISCUSSION

The concentrations in the plasma, with a peak of 0.75 μg./ml. 90 minutes after the drug administration, are comparable to those observed by others. If distributed uniformly, the drug concentration would be about 16 mg./L of body water (assuming

80% wet weight). The highest observed concentration (0.75 μg./ml.—9.75 mg./L) is 1/47 of this value. This discrepancy presumably results from the rapid binding of the drug by the tissues, primarily brain tissue.

The milk levels were barely above the detectable level. The concentrations paralleled that of the plasma, an observation similar to that found with other drugs. However, the highest concentration in the milk was less than half that in the plasma, 0.29 μg./ml. at 120 minutes, and its appearance lagged behind that in the plasma.

From the data we have calculated that an infant might have received 10 μg. Cpz. in the total amount of milk (124 ml.). In the seven-pound child this would have been a 3 μg./kg. dose. The pediatric dosage for Cpz. is ¼ mg./kg. (250 μg./kg.) every 4 to 6 hours. It appears that the amount of chlorpromazine an infant could have received from nursing would have been insignificant.

Several times we administered 600 mg. of chlorpromazine orally but could not detect the drug in the blood nor the breast milk, nor could we measure chlorpromazine in the morning milk sample after the patient had been maintained on 600 mg. b.i.d. for 7 days. The tissues rapidly take up small amounts of the drug, and apparently a large single dose is needed to give a detectable blood or milk level. Hence it may be suggested that an increased margin of safety could be given the nursing infant by prescribing chlorpromazine in the Spanule form.

There seem to be advantages in allowing some postpartum psychotic patients to participate in the care and feeding of their children. In the case of this young woman, her ability to breast-feed her child was important to her and seemed to speed her recovery.

SUMMARY

The amount of chlorpromazine was measured in the breast milk of a lactating psychotic woman after 1200 mg. Cpz. was given in a single oral dose. The microgram amounts found were probably insignificant physiologically. Our study suggests that babies of mothers receiving large doses of chlorpromazine can be safely breast-fed.

EFFECTS OF CHLORPROTHIXENE¹ IN WELL-ESTABLISHED SCHIZOPHRENIC REACTIONS

IRENE K. GAYUS, M.D., AND JAMES E. BLANCHETTE, M.D.²

Although psychopharmacological agents have had little influence on the underlying pathology of schizophrenics(1), they have been instrumental in lessening anxiety-tension, modifying behavior, and bringing patients into contact with reality long enough to develop some degree of interpersonal relationship with the therapist(2, 3). In fact, the use of such agents has enabled many patients once considered permanently isolated from reality to participate actively in hospital life, carrying out meaningful tasks within the confines of an institution.

In most instances the phenothiazines have been the drugs of choice in these patients, but while generally effective, they are not without limitations. The development of severe toxic reactions frequently overshadows if not negates the benefits obtained with these drugs, and in many patients little if any improvement is noted even in the absence of untoward effects. Thus, there is pressing need for drugs equal or superior to the phenothiazines in efficacy but substantially lower in toxicity and somatic effects. With this in mind, we became interested in a new thioxanthine derivative, chlorprothixene, a drug which has shown great promise in studies conducted here and abroad(4-10), particularly in patients with psychosis and severe psychoneurosis characterized by agitation and depression.

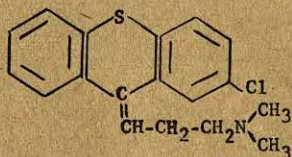

Chlorprothixene is 2-chloro-9-(3-dimethylaminopropylidene) thioxanthine, structurally resembling chlorpromazine; how-

ever, it is more potent than chlorpromazine and unlike any phenothiazine derivative, it appears also to exert a marked effect on psychogenic depressions(7, 10). The low incidence of side effects and adverse reactions reported for chlorprothixene, especially the absence of parkinsonian symptoms and liver or kidney dysfunction, would seem to indicate that it has a considerably lower toxic potential than the phenothiazine derivatives. We therefore set up a study to investigate its influence, if any, on a series of patients with severe advanced schizophrenic reactions.

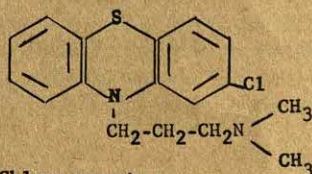

MATERIALS AND METHODS

Thirty female patients, ranging in age from 30 to 50 years (average 45.2 years), at the Patton State Hospital, Calif., were selected for the study. Twenty-nine had been diagnosed as schizophrenic, including 10 paranoid, 8 hebephrenic, 4 catatonic, 2 chronic undifferentiated, 2 acute undifferentiated, and 1 each simple, residual, and schizo-affective; 1 patient was diagnosed as manic-depressive. These conditions were of long standing, namely from 2 to 25 years (average 12.5 years), and in 6 patients for over 20 years. Previous therapy had consisted of Thorazine, Trilafon, Stelazine, Compazine, Sparine, and Librium; 3 patients had also received EST. Response to these medications and therapy had been fair to poor.

On the first day Taractan was admin-

Chlorprothixene

Chlorpromazine

¹ Manufactured as Taractan®, Hoffmann-La Roche Inc., Nutley, N. J.

² Respectively, Staff Psychiatrist, Chairman, Research Committee, Patton State Hospital, Patton, Calif.

istered following breakfast in a single dose of 100 mg., which proved to be too concentrated. On the second day the same total dosage was divided into 4 doses of 25 mg.,

with no complications. In time the maintenance dosage was increased to from 200 to 700 mg. daily in divided doses. Therapy was maintained for 60 days in 1 patient and for over 90 days in the remaining 29. Adjunctive therapy included thyroid in 2 hypothyroid patients, some degree of psychotherapy in all, and, occasionally, such measures as necessary to protect the patients from themselves and each other, *e.g.*, seclusion, restraints, close supervision.

The patients were subjected to regular blood analysis and hepatic and renal function tests; careful note was also made of any cardiac arrhythmias, changes in blood pressure, or skin reactions.

The results were evaluated on the basis of improved social behavior, cooperation, mood elevation, socialization, and diminution of hallucinotic and delusional experiences.

RESULTS AND CASE HISTORIES

Eleven of the patients had good to excellent results. They showed definite social improvement, maintained throughout therapy. There were marked tranquilizing and antidepressant effects which eradicated hostile, anxious, belligerent, and other asocial behavior. In some of these same patients Taractan acted as an energizer. Five of the 11 are performing work assignments with zest and efficacy, and 4 lethargic, quite deteriorated women developed marked stimulation and increased energy output, carrying out various tasks entirely on their own initiative. In these patients the energizing

effects in no way interfered with relaxation or cooperation. To a lesser extent hallucinations were diminished and delusions suppressed or eliminated.

In the 6 patients with fair response, there was improvement in some ways: they became more pleasant, calmer and less noisy; cyclothymic changes occurred less frequently and previously helpless women began to dress without assistance and take more personal interest in themselves. There was, however, no change in hallucinosis or confused thought patterns, and it was still impossible to maintain contact with them for an extended period of time.

Thirteen patients remained the same or became worse while on Taractan. Occasionally one of these patients would become less agitated or eat better, but there was no real change in their status. Restraints and isolation had to be continued in most, as well as close supervision in all. The results are summarized in Table 1.

There were few side effects. Due to the large initial dose almost all developed vertigo, 2 had convulsions, and 1 a grand mal seizure. However, when the daily dosage was divided into 3 to 4 smaller doses there was no repetition of symptoms even on dosages as high as 700 mg. per diem. Later in therapy 1 patient fainted, and another hypothyroid patient developed edema of the eyelids and cheeks. This subsided when thyroid was administered and the Taractan dosage reduced. Taractan had to be discontinued in one patient, a schizophrenic reaction paranoid type, who became maniacal and had to be isolated and

TABLE 1
Diagnostic Categories and Results of Taractan Therapy

restrained. After cessation of therapy she recovered but again became maniacal when the drug was resumed.

Laboratory studies did not reveal evidence of hepatic, renal, or hematologic changes, nor were there signs of parkinsonian symptoms, cardiac arrhythmias, altered blood pressures, or suppressed sensorium. Also there were no changes in EEG's of the 3 patients who had convulsions.

The patients studied were among the most disintegrated, hopeless psychotics in the unit. Nevertheless over 56% of them achieved some symptomatic improvement, 36% obtaining good to excellent response. The degree and type of improvement are best illustrated by the following, brief histories.

Case 5. K.G., a 42-year-old woman with depressive reaction of 9-years' duration, was quiet and noncommunicative, spending her time rocking back and forth. After the initial 100 mg. dose of Taractan she developed convulsions, but these disappeared when the divided doses were given. During the next 20 days she was maintained on 200 mg. per diem and was observed to brighten up and make friendly gestures towards the other patients and the hospital personnel. The dosage was increased to 300 mg. during which time she showed increasing improvement. She still rocks on occasion, but maintains her pleasant, friendly attitude and carries out various assigned tasks satisfactorily.

Case 7. D.B., a 45-year-old woman with schizophrenic reaction, paranoid type, of 3-years' duration, was a belligerent, antagonistic patient who slept much of the time and refused to carry out any work tasks. Thorazine medication had proved useless. She developed convulsions after the first Taractan dosage, but did well on a maintenance dosage of 100 mg. per diem for 20 days, and later on 450 mg. for 42 days. She is now a friendly cooperative patient, works well and has become one of the best kitchen workers in her unit. She is presently being kept on 150 mg. t.i.d.

Case 9. J.B., a 50-year-old widow with schizophrenic reaction, paranoid type, of 9-years' duration, was completely out of contact with reality, believed that she and her husband were doctors, and went about pulling bats out of the atmosphere. She had responded poorly to Stelazine therapy. The patient was maintained on 100 mg. Taractan daily for 10

days with little response, after which the dosage was increased to 500 mg. per diem. She responded very well to this increase and now talks much more normally with only occasional word salads. She still has delusions concerning her husband but for the first time is able to carry out assigned tasks. She is being maintained on 200 mg. per diem.

Case 13. M.B., a 48-year-old woman with schizophrenic reaction, hebephrenic type, of 22-years' duration, was a childlike, withdrawn person who had to be spoon-fed and closely watched for incontinence. She had obtained only slight improvement after Stelazine therapy and EST. However, her response to 100 mg. Taractan per diem was good, and it improved steadily as the dosage was increased gradually to 600 mg. For the first time she wrote letters home and took an interest in various unit activities. Through her own efforts she improved her appearance using cosmetics and visiting the beauty parlor. When the present study terminated and Taractan was discontinued, she disintegrated rapidly. She has since been reinstated on Taractan.

Case 21. M.W., a 45-year-old woman with schizophrenic reaction, catatonic type, of 24-years' duration, was belligerent, sat by her bed all day, yelling, pounding her head, and refusing to do anything but eat. There had been no response to previously administered liquid Thorazine. While on 100 mg. Taractan she became quieter and less hostile, but developed syncope on the 7th day of therapy. However, this cleared up almost immediately, and further improvement followed after a dosage increase to 600 mg. per diem. At present she is only occasionally belligerent and has developed great interest in the cooking group.

COMMENT

The overall response to Taractan therapy was more than satisfactory. It is not surprising that many patients failed to improve since those investigated represented the most far-removed from reality and least likely to obtain remission. Still, it is noteworthy that those who did well had previously responded poorly to the phenothiazines, the only other agents available that might have been of benefit. In addition, it was felt that the study had progressed only to the stage where contact was made with the patients; indications are that better socialization and cooperation in psycho-

therapy may be expected in the future.

For the present, Taractan appears to be a safe but potent drug. Its influence, if any, on underlying psychic pathology has not been demonstrated, but it does effect a favorable outcome in the symptomatology of certain psychoses characterized by agitation. Further study on the possible applications of Taractan are strongly recommended.

COMMENTS

SOVIET PSYCHOLOGY

This is the title of a recent book by five prominent Russian educators (translated by Ralph B. Winn and published by Philosophical Library) that western psychologists will profit by reading; and not psychologists only but all who have responsibility in teaching and training children and youth.

The text provided by these five teachers runs to only 99 pages. They have therefore reduced the subject of Soviet psychology to its simplest terms, often by the use of dogmatic assertions that brook no questions: "Only dialectical materialism has a correct conception of the nature of experience . . . It alone emphasized the historical nature of consciousness and revealed the class character of consciousness in a class society . . . It decisively rejects all theories which argue that man's personality and experience are determined by biological, natural drives."

The question of the respective parts played by heredity and environment in shaping personality is resolved quite simply and finally in favor of "the correct view of the decisive role of the environment." If any doubt remains we are informed that "the Central Committee of the Communist Party of the Soviet Union passed the resolution of July 4, 1936. This resolution . . . put an end to the 'two-factor theory' which proclaimed the equal role of heredity and environment." John Dewey was of course all wrong in his "erroneous view of the strength of biological factors." It is freely admitted that Soviet psychology, based on Marxist theory, is not yet fully developed and that there is need of further studies "of the basic changes in human experience produced by the abolition of private property and by the planned transformation of this experience under conditions of gradual transition from socialism to communism."

The simple thesis throughout this primer is the moulding of the child's mind from its

earliest years, consistently and continuously, to the frame of the class society of Soviet Russia. "This change in the activities and relationships of the child, the juvenile and the adult, is a process whose course is not evolutionary. It rather takes the form of sudden transformations." Throughout the educational process "bourgeois psychology" is rejected and replaced by "Marxist theory."

"The play of our Soviet children becomes, therefore, a school in which they practically acquire the norms of Socialist behavior."

If we disregard for a moment the narrowly unilateral purpose and the end product of Soviet education, we find details worked out in this system of training which should be considered basic anywhere and to which education planners in the western world might profitably pay more attention. These details have to do with the integration of the child in the "family collective," developing in him from the beginning an awareness that he is not only an important but also a responsible member of the family, with suitable daily duties just as father and mother have their daily work. The child not only receives; he also earns. This discipline of home life is intended to prepare for school life and to obviate behavior disturbances due to incompatibilities between school discipline and home discipline. Instilling the sense of duty is paramount throughout in shaping the child's personality—"the personality of a Soviet patriot and of a future fighter for Communism."

Taking full account of worthwhile features of Soviet psychology, of which the contributors to this book seem to feel that they have a monopoly, it may be suggested that their dogmatic rejection of "fatalistic Western psychology" is hardly in keeping with the spirit of science that recognizes no national boundaries.

CORRESPONDENCE

CARDIAC ARREST

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : In the February 1962 issue of the *American Journal of Psychiatry* on p. 753 there is an exchange of letters discussing the treatment of cardiac arrest occurring during or under electroshock therapy. These letters were drawn to my attention because of the inherent danger of some of the statements made by the writers. Experimental studies by Kouwenhoven and others have shown that external closed chest defibrillation can be accomplished only by the use of a high voltage current (Kouwenhoven, W. B., *et al.* : *Surgery*, 42 : 550, Sept. 1957). It has been found that that which is most effective for the adult is 440 volts for 0.25 seconds. Low voltage currents, such as are usually delivered by EST machines, have, when placed across the closed thorax of the experimental animal, caused ventricular fibrillation. Such low voltage shocks, however, when sent across the *heart only* with the *chest open* can defibrillate the heart in ventricular fibrillation. The actual current going through the heart required to defibrillate it is 1.5 to 2 amperes. This can never be delivered through the closed chest unless the voltage is as high as mentioned above.

I agree wholeheartedly with the writers that a well oxygenated myocardium is necessary before defibrillation is possible or before the heart beat can be re-established even if the heart is only asystole. It is of greatest importance when circulatory arrest is considered that both ventilation by

mouth-to-mouth or other techniques and circulation by external cardiac massage be immediately applied. Other assistance from cardiologists and surgeons can be obtained as long as both ventilation and circulation are artificially provided continuously.

The injection of epinephrine into the cardiac musculature was mentioned. If 3/10 or 5/10 mgm. epinephrine is to be injected (and this is very valuable) it should be into *the blood* of the heart and then circulated throughout the coronaries and the rest of the body so as to give a stimulating action to the entire myocardium. Localized injection into the heart musculature will cause an irritative focus and may result in ventricular fibrillation if it is not already present. Such drugs injections should follow and not precede support of the oxygenation system by artificial ventilation and artificial circulation. In a recent article (Jude, J. R., Kouwenhoven, W. B., and Knickerbocker, G. G. : *J.A.M.A.*, 178 : 1063, Dec. 1961) the procedure and stepwise treatment for sudden circulatory arrest is described.

While cardiac arrest is rare under EST but does happen, with proper treatment resuscitation should occur without difficulty.

I hope you are able to publish this letter in an early issue of your *Journal* so as to forestall the possible harmful use of the electroshock therapy machine as an external cardiac defibrillator.

James R. Jude, M.D.,
Baltimore, Md.

REPLY TO THE FOREGOING

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : It has been almost two years since I used the electroshock machine in an attempt to restimulate a heart that had entirely ceased beating. Subsequently much

research has been done by others.

Since that time the technique of external cardiac massage has been developed. The evidence that Dr. Jude offers seems to indicate that the use of the electroshock machine in an attempt to restimulate the

heart following cardiac arrest is contraindicated. It looks as if my single experience was a lucky one.

I am extremely grateful to Dr. Jude and others for their comments. Such exchanges of information between various branches of medicine have contributed substantially to

our knowledge. I sincerely hope that my observation which I reported led to no harm. At least it provided stimulus, even if in a negative fashion.

Corbett H. Thigpen, M.D.,
Augusta, Ga.

SUICIDE IN ADOLESCENTS

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: In the article, "Suicide and Suicidal Attempts in Children and Adolescents" (J. M. Toolan, Feb. '62), it is stated (p. 719), "There have been *only two* recent studies on the subject of suicidal attempts by adolescents." It goes on to cite Mason (1954); and, Balser and Masterson (1959).

May I correct the statement by calling your attention to the fact that the paper, "Events and Conscious Ideation Leading to Suicidal Behavior in Adolescence" (H. I. Schneer, P. Kay and Dr. Brozovsky) published in the *Psychiatric Quarterly*, July 1961, was read Nov. 28, 1959 at the New York State District Branches meeting of the APA and was excellently reported in the N.Y.S.D.B. Newsletter (April 1960). Dr. Toolan's paper was read May 1961. In the

book, *Adolescents: Psychoanalytic Approach to Problems and Therapy*, a chapter (9), The Suicidal Adolescent, by H. I. Schneer and P. Kay, appears and was published in April 1961. It is of interest to note that Dr. Toolan at Bellevue Hospital reports 84 suicidal adolescents (12-17 years of age) during 1960. It is difficult to derive a rate for adolescents since Dr. Toolan combines children and adolescents in the quantity "approximately 900 admissions." He gets a rate of 11% of all admissions under 16. From our material during 1956 and 1957 we (Schneer, Kay, Brozovsky) reported 84 suicidal adolescents (12 to and including the 16th year) of 653 adolescent admissions (12-16) yielding a rate of about 12%.

Henry I. Schneer, M.D.,
State University of New York,
College of Medicine.

REPLY TO THE FOREGOING

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: Dr. Henry Schneer states that I did not refer to his paper "Events and Conscious Ideation Leading to Suicidal Behavior in Adolescence," published in the *Psychiatric Quarterly*, July 1961. This is certainly correct. Dr. Schneer knew that my paper was read and presented at the annual meeting of the American Psychiatric Association,

May 1961, two months prior to publication of his article. He also called my attention to his book *Adolescents*, published April 1961. Unfortunately, Dr. Schneer's book had not been brought to my attention prior to the writing of my paper.

James M. Toolan, M.D.,
New York University,
College of Medicine.

NEWS AND NOTES

MISS SWITZER HONORED.—Miss Mary E. Switzer, Director of the Office of Vocational Rehabilitation of the U. S. Dept. of Health, Education, and Welfare, received the honorary degree of Doctor of Humanities from Duke University at its commencement, June 4.

This was her seventh honorary degree. She received previous years Doctor of Humanities degrees from Tufts University (Massachusetts), Gallaudet College (Washington), Boston University, and Western College for Women (Ohio), the Doctor of Laws degree from Adelphi College (New York) and the Doctorate of Medical Science from the Women's Medical College of Pennsylvania.

Miss Switzer is the first woman ever to receive the coveted Albert B. Lasker Award for international work for the disabled; she has also received other outstanding awards for work with the handicapped and has been given the President's Certificate of Merit, the highest award given to a regular civil service employee. As a representative of the United States at the first International Health Conference, Miss Switzer helped to develop the constitution of the World Health Organization.

OF HOGS AND HUMANS.—In an open letter from the President of Smith Kline & French Laboratories, the statement is made, "Not long ago, Secretary of Health, Education, and Welfare Ribicoff remarked that men, women and children should receive the same protection against the marketing of worthless drugs as hogs, sheep and cattle.

"His statement made headlines and was repeated in a Presidential message to Congress. It undoubtedly created a strong public impression that animals are protected by law against bad medicine and that humans are not. But the facts are otherwise."

The open letter continues, "Medicines for animals and human beings alike are regulated by two sets of laws, one covering biological products such as serums and vaccines, the other covering nonbiological

medication usually dispensed in the form of tablets or capsules.

"In this Act (the Virus, Serum, and Toxin Act of 1944) . . . the Public Health Service is given authority to insure 'the continued safety, purity and potency of biological medicines.'

"With respect to other medicines, both animals and humans are protected by *exactly the same law*—the Food, Drug, and Cosmetic Act of 1938.

"Obviously, then, hogs do not receive greater protection than humans. This is the fact of the matter, and when the fact pertains to such a vital question as the public health, it is important to keep the record straight."

RESEARCH TRAINING IN PSYCHIATRY.—A 2-year program leading to the degree of Doctor of Medical Science is offered by the Graduate Educational Program of the State University of New York, Downstate Medical Center. The program is open to M.D.'s who have completed 3 years of residency training in psychiatry. Candidates who have completed 2 years of residency will also be accepted by special arrangement. The program provides a series of courses concerned with research methods and current major concepts in psychiatry.

Each candidate accepted will be granted a fellowship of \$6,000 for the first post-residency year and \$7,000 for the second year. These fellowships may be supplemented by stipends for special research or teaching. Applications for the academic year beginning September 1963 should be submitted before February 1, 1963. For additional information write to: Office of Admissions, Downstate Medical Center, 450 Clarkson Avenue, Brooklyn 3, N. Y.

CORRECTION.—It is regretted that the appearance of two figures, which replaced two others originally submitted with the manuscript, was accidentally reversed in the printed paper. In the May '61 issue Figure 13 on page 1024 should have been placed

on page 1023 under the heading "EEG Recordings (Cortical and Subcortical) from Patient #A-26 during Period of Remission," and Figure 12 on page 1023 should have been printed on page 1024 under the heading "EEG Recordings (Cortical and Subcortical) from Patient #A-26 during Period of Psychosis."

CORRECTION.—It is regretted that in setting up the list of new Diplomates of the American Board of Psychiatry and Neurology, which appeared in the June issue of the *Journal*, the printer omitted the name of David Abrahams, M.D., Los Angeles, which should have appeared initially in the list under Psychiatry.

RESEARCH ADMINISTRATION

JOHN R. WHITTIER, M.D.¹

The subject of research administration is not taught in medical school or residency, or an experience gained in private practice or in teaching. Over a period of years, the writer has accumulated a list of readings on the subject, with special reference to psychiatry. A selection from the list is offered herewith.

BOOK REVIEWS

PREHISTORIC MAN. By *Josef August*, and *Zdenek Burian*. (New York: Tudor Publishing Co., 1961, pp. 52, plates 52. \$9.95.)

The senior author of this book is a professor of paleontology and the junior author the artist who prepared the beautiful colored plates representing the forms and life of prehistoric man and his precursors. The book is a product of Czechoslovakia, and it speaks volumes for that country's technical achievements in being able to produce a book of such attractive appearance. Unhappily the book is marred by some serious misrepresentations of some of the types it represents. *E.g.*, Neanderthal Man is represented in a form which I have been arguing against for a generation. Recently Cave and Straus, re-examining the skeleton of Neanderthal Man, have shown that the traditional conception of him as a knock-kneed, bow-legged, bull-necked, stooped-walking, club-wielding monster is wholly contrary to the evidence. Nevertheless, Neanderthal Man is so reconstructed in this volume. We are also misinformed to the effect that the Neanderthals did not adorn themselves with any ornaments and left no cultural relics to posterity. These statements, also, are contrary to the known facts; nor was Neanderthal Man the first human being to appear on earth. There are numerous other misstatements, and it is all a great pity, because Mr. Burian is an artist of great ability, and his illustrations are for the most part beautiful, but alas, it is all to no purpose, since the bestiality of early man is overemphasized, and one comes away from this book with the false impression that early man was a nasty sort of creature. The conclusions usually drawn depend upon the temperament of the drawer, one is that innate nastiness is the common human heritage, the other is that we have evolved from nastiness to comparative un-nastiness. Both conclusions, I believe, are wrong, and it is books such as this that help to perpetuate such wrong ideas.

A great deal of labor and talent went into the making of this book. The artist has done much better than the author of the text. It is a pity that both of them did not avail themselves of the existing knowledge which would have prevented them from committing the scientific solecisms they have.

ASHLEY MONTAGU, PH.D.,
Princeton, N. J.

THE SOCIOMETRY READER. Edited by *J. L. Moreno, M.D., et al.* (Glencoe, Ill.: Free Press, 1960, pp. 772. \$9.50.)

What happens to people is somehow related to what happens between people. Psychiatry is a social science. Moreno has, perhaps more than any one else, developed the study—particularly the measurement—of contact lines between people. This book consists of 64 papers (14 of them by Moreno) on various aspects of sociometry. To the clinician, many of the articles will seem turgid with abstract concepts, hard-to-follow sociograms, and a rather esoteric jargon. (Example: "Cultural conserves are products of creativity, antipodal to spontaneous matrices which emerge in the intensive heat of status nascendi.")

Sections cover definitions, historical background and method. There is material on sociometric choice, the sociomatrix, derivations of status index, distribution of isolates, measures of reciprocation, matrix algebra, interpersonal desirability values, and so on.

As with all anthologies, the style varies. Some of the chapters are written with transparent clarity; others are utterly obscure. Little of the material is of everyday clinical value, but a mastery of the sociometric concepts will give any psychiatrist a better philosophic foundation. On the whole, this book makes hard reading. To grasp it, you have to sweat over some of the pages. But it is loaded with ideas. It is a volume to be tasted. It certainly cannot be gulped.

HENRY A. DAVIDSON, M.D.,
Cedar Grove, N. J.

FIELD STUDIES IN THE MENTAL DISORDERS. Edited by *Joseph Zubin, Ph.D.* (New York: Grune & Stratton, 1961, pp. 495. \$6.75.)

COMPARATIVE EPIDEMIOLOGY OF MENTAL DISORDERS. Edited by *Paul H. Hoch, M.D.*, and *Joseph Zubin, Ph.D.* (New York: Grune & Stratton, 1961, pp. 290. \$9.75.)

These two books go together. The first is the verbatim report of a Work Conference, held under the auspices of the American Psychopathological Association; the second is similarly the report of the 49th annual meeting of that Association, held immediately after the Work Conference, February 1959.

Those participating included distinguished

representatives of the psychiatric profession in Europe, as well as distinguished epidemiologists, vital statisticians, and biometricians, from both the U. S. A. and Europe. The proceedings consisted of formal presentations, extensive discussions, often with additional material, and summaries of the various sessions. The reader thus finds here descriptions of methods used and results obtained in various studies in various parts of the world at various times, as well as various views from various schools. And he finds disagreement on practically everything—diagnosis, prognosis, nomenclature, methods and even results of surveys and studies. Some participants called for new methods, new approaches, but others cautioned against complete disregard of the past and made a plea for continued, intensive, competent study. In spite, or because of, the disagreements, there is very much here of high value for general epidemiologists and statisticians, as well as for psychiatrists and psychologists.

The index in each volume is complete, and the general set-up and printing of high order.

N. E. MCKINNON, M.D.,
University of Toronto.

50 JAHRE NEUROPATHOLOGIE IN DEUTSCHLAND, 1885-1935. Edited by *Prof. Dr. W. Scholz*. (Stuttgart: Georg Thieme Verlag, 1961, pp. iv + 123, illus. DM 12.80.)

This valuable compendium was a gift of the first Congress of Neuropathology to be held in Germany to the accredited members of that Congress recently convened in Munich. This was made possible by a grant from the World Federation of Neurology. A finer text with photographs of individuals and groups of pioneers in the Fach to serve as a background to the Congress can hardly be imagined.

Here are the life stories of the small group of great German innovators who founded and built up the anatomy, pathology and histopathology of the nervous system, with special attention to the central organs and the cerebral cortex, and particularly as a basis, so far as possible, for clinical understanding. It was a new division of science made possible by new techniques and staining methods developed by men who created that science—Weigert, Edinger, Nissl, Alzheimer, Spielmeier, Brodmann and the Berlin group.

In the midst stands the name of Emil Kraepelin, of whom Professor Kurt Kolle, referring particularly to the Heidelberg and Munich members of the group, writes: "These

brilliant men would never have been able to accomplish what they did without this forceful man who drew them to his Heidelberg Clinic, his Munich Clinic, and later to his Research Institute—not without Kraepelin . . . Besides being a clinician of great distinction Kraepelin must also be reckoned as a co-founder of neuropathology."

Nissl stands out especially among these men. It was he who by means of his refined methylene blue stain discovered in the bodies of the nerve cells the particles which he described as the "sogenannte granula," but which others promptly christened the Nissl bodies—and so they are to this day.

Of the group around Kraepelin he was the first to join him at Heidelberg, soon to be followed by Alzheimer. Nissl founded the *Histologische und Histopathologische Arbeiten ueber die Grosshirnrinde*, the first volume of which came out in 1904. This 500-page book contained two separate papers by Alzheimer and Nissl on the histopathology and differential diagnosis of general paresis. These greatly detailed studies were illustrated by beautiful oil-immersion pen drawings in color by the authors together with photomicrographs of the cortex and other pictures in the text. The *magnum opus* of the two pioneers was the last word in the description and illustration of the gross and finer pathology of paresis.

One reads here also the tragic story of Franz Nissl's break with his father, a confirmed Catholic, who intended his eldest son for the priesthood, introduced him to the philosophy of Thomas Aquinas, and forbade him to attend a North German university, fearing Protestant influences. Nissl however was not diverted from his chosen course. In his room in the Heidelberg Clinic he replaced the crucifix over the bed with a self-designed motto which read "Ecrazez. Rottet sie aus."

It was Weigert who stood at the head of this pioneer group as being the oldest. In his laboratory in Frankfurt a/M., Edinger, Nissl, and Alzheimer did their own early work and gladly acknowledged their indebtedness to the master. There they learned of the long laborious steps in the development of the Weigert stain for the myeline sheath, and glia fibres, the staining method that was always "beinahe fertig."

During a life of many and heavy vicissitudes Weigert maintained his cheerfulness and his devoted work up to the time of his sudden death at 58.

The men who are memorialized in this book—for the production of which we have to thank Professor Scholz of the Forschungs-

anstalt in Munich at Kraepelinstrasse 2—were the builders of neuropathology in Germany during the closing years of the nineteenth century and the early years of the twentieth. It was the reviewer's great privilege to be in Germany in the midst of that germinal season and to have worked under the guidance of Kraepelin, Nissl and Alzheimer during the Heidelberg period. Appreciation of the value of that experience has grown with the passing years. There were giants in those days, and one cannot but think of how it might have seemed to have stood on the face of the planet in its earlier days when the mountains were thrusting up.

C. B. F.

THE ABNORMAL AND THE MENTALLY ILL BEFORE PENAL JUSTICE. By A. Porot, and Ch. Bardenat. (Paris: Librairie Maloine, 1960, pp. 259.)

As is evident from its title, this book is a work in legal medicine, and both aspects, law and medicine, are covered in great detail. Like most European texts, the psychiatric concepts abound with references to numerous authors, most of whom are French. They discuss the extent of penal responsibility. Irresponsibility is defined in article 64 of the French Penal Code as a state of dementia at the time of the act or as a restraint by a force that the person involved could not resist. The value of the testimony of experts is discussed. Among the states of constitutional deficiencies they list: idiocy, imbecility and mental retardation. The social ethnic retardation (paleophrenia)*causes a deficiency in the power of criticism and judgment and in the sense of relationship this brings stupid conclusions, credulity and suggestibility. They also list a group of sensory inferiorities (mutes and deaf-mutes).

The French have a term, "desequilibres," which may be rendered in English by "unstable." It has been used by Regis and Borel and denotes irregular and capricious behavior, a lack of efficiency, numerous faulty acts, and a poor social adaptation that leads to delinquency. This instability is brought about by the special constitutional structure of the personality, causing cyclothymic, paranoid, epileptoid and psychasthenic "dispositions." One can already note that the French psychiatric terminology differs substantially from that used in the United States.

There is also an instability in the moral field: amorality and perversions. Character instabilities are aggressiveness, compulsion-obsessiveness (including specific sexual behavior), kleptomania, pyromania and destructive-

ness. Instability in the ideational field expresses itself through mythomania and fabulation. Instability in psychomotor activity may be permanent or temporary: fugues and cravings to travel (dromomania). Among the psychoneurotic reactions that mitigate guilt are various states of anxiety and passion, hysterical suggestibility, hypnotic states and obsessions. Cenesthesias are subdivided into neurasthenias and cenestopathies, terms that are seldom used among us. The sexual perversities discussed are eroticism, frigidity, impotence, homosexuality, incest, rape, bestiality, masochism and sadism. In this group the problem is less in the definition of guilt than in the definition of the act.

Juvenile deficiencies combine various forms of dementia praecox (Morel), which was once equated with hebephrenia (Hecker). Schizophrenia was coined by Bleuler to denote the disassociation of the different psychic functions. Senile dementias may begin precociously at fifty as the presenile dementias. But cerebral atherosclerosis may start as early as forty. This is very important in establishing penal responsibility. Organic mental deficiency states and cranio-cerebral traumatism are easier to establish. Acute manias and other states of excitement and hallucinations are treated together with epilepsy, alcoholism and intoxication. Of particular interest to psychiatrists is the ample treatment of psychopathological reactions to the trauma of imprisonment.

PSYCHIATRIE DER GEGENWART—FORSCHUNG UND PRAXIS. Volume III. Social and Applied Psychiatry. (Edited by H. W. Gruhle, R. Jung, W. Mayer-Gross, and M. Müller. (Berlin: Springer-Verlag, 1961, viii, pp. 880.)

The second volume of this work—*Clinical Psychiatry*—has been reviewed here. The first volume is likely to be published soon. In this volume the authors deal with Social and Applied Psychiatry. Under the heading Social and Practical Psychiatry, new movements, suicide, organization of hospitals and nosological problems are discussed. There are contributions in English by Paul H. Hoch (New York), by Kenneth Soddy (London, England), and by Sir Aubrey Lewis (London, England), on social psychiatry, mental hygiene and psychiatric educational training, respectively.

The second chapter, Forensic Psychiatry, has sections on forensic and administrative psychiatry, on sexual perversions by J. Wyrsech (Bern), and a review in English on forensic psychiatry in various countries by Gösta Ry-

lander (Stockholm).

The third chapter, *Borderland of Psychiatry*, brings an English paper on psychiatry and ethnology by Margaret Mead (New York), a paper on religion and psychiatry by a Swiss author (Hans Heimann) and a very good treatise on art and psychiatry in French by Robert Volmat (Besançon, France).

In the fourth and last chapter, the psychiatry of wartime is presented. There are many aspects of great interest in every sphere and on every level of the fighting soldier, the war prisoner, the fugitive, the civilian, and the concentration camp. The frustrating and often desperate attempts to take new roots after losing one's original ones, and the problem of changing roots again (*Umwurzelung*) are discussed. Acute damages due to hunger and their neurological and psychiatric sequelae, as well as neuropsychiatric disorders in prisoners-of-war are presented, the latter in English by E. K. Cruickshank (Kingston, Jamaica).

This is an impressive volume with many facets, which really renders a picture of modern psychiatry in all the fields dealt with so far. The numerous bibliographic references are particularly helpful, too. The two remaining editors—R. Jung and Max Müller—are the more to be congratulated as, since the appearance of the second volume, two of the original editors—H. W. Gruhle and W. Mayer-Gross, both excellent men whose deaths were serious losses—died.

EUGEN KAHN, M.D.,
Houston, Texas.

THE PRACTICE OF MENTAL NURSING. 3rd Ed. By *May Houlston*. (Edinburgh: E. S. Livingstone; Baltimore: Williams & Wilkins, 1961, pp. 164. \$3.00.)

The author has indicated in the preface to the third edition that this book has been written primarily for the junior student nurse in the mental hospital. Emphasis is placed on nursing practice in England, Wales and Scotland.

Miss Houlston has covered a wide range of subject matter, including an historical survey of mental illness, essential qualities and general duties of the mental nurse, normal psychology, general symptomatology of mental disorders, mental and physical factors in mental disorders, cleanliness of patient, night nursing, *etc.* The attempt to include such a wide range of content in a small book has necessitated compressing some valuable content in a few short paragraphs. Areas such as the specific procedures for "blanket bathing" and "care and administration of dangerous drugs and

poisons" are presented in considerable detail.

The author has stated that the most important part of the book deals with practical nursing. Undoubtedly, this is the reason considerable emphasis has been placed on nursing procedures. The content in psychiatry and psychiatric nursing is presented in an introductory fashion. A comprehensive summary is included at the end of each chapter. Worthwhile suggestions are offered for nursing activities in recreational and occupational therapy. A short bibliography is included.

This book contains a good deal of elementary general nursing content and would be most useful to the beginning nursing student practitioner.

New York, N. Y.

MULTIPLE SCLEROSIS (PROGNOSIS AND TREATMENT). By *Leo Alexander, Austin W. Berkeley, and Alene M. Alexander*. (Springfield, Ill.: Charles C Thomas, 1961.)

The authors review in details the events from 1948 to 1956 in the life of a large group of patients with multiple sclerosis. The cases were carefully selected and a special rating scale of disability was used in following them. The authors attempt to use precise criteria for evaluation of the course and response to several types of treatments in specific groups of patients. Much use is made of modern statistical methods which makes some difficult and laborious reading for a clinician. The clinician will, however, have no trouble in following the main conclusions of the authors which may appear to be better validated than is actually the case; only a medical statistician could evaluate some of the conclusions. This is a unique study in America and, in general, supports much of the classical work of McAlpine and colleagues in England.

The authors do suggest quite strongly that ACTH and the use of blood transfusions in selected patients control the disease or bring about remissions. The method of selecting the patients for, and the technique of giving, each type of treatment are outlined. However, it is evident that further study of such treatments in other centres is needed before physicians can accept such therapy without qualification. In general, the monograph is well organized and many neurologists and others familiar with multiple sclerosis will find it interesting. The scoring method for disability rating may prove useful in studies by others who attempt to evaluate treatment but some simplification of it seems desirable.

EARLY SWISS SOURCES OF ADOLF MEYER'S CONCEPTS¹M. BLEULER, M.D.²

Adolf Meyer had the benefit of a good medical training in Switzerland. Towards the end of his studies he worked—but only for a short time—at the Burghölzli in Zürich under August Forel, one of the most outstanding psychiatrists of his day. Afterwards Meyer did indeed gather experience from many places, but during his education he never remained for a long period under the influence of a single important clinician or an outstanding psychiatric school. In a certain sense he was a self-taught psychiatrist. In any case, he never took over the ideas of another psychiatrist to develop further his own epoch-making concepts.

However, even the greatest men do not create in a vacuum but have ties with the ideas of preceding generations. Up till now we have known little of the great intellectual currents by which Adolf Meyer was influenced. That he himself did not tell us much is perhaps related to the frequent reluctance of Swiss emigrants to advertise their Swiss origins in the new land.

In conversation with his Zürich relatives (the descendants of his cousin) an intellectual tie was revealed between Adolf Meyer and a man who lived in the Canton of Zürich in the 18th century and whose fame spread far—Jakob Gujer, known as Kleinjogg or Little Joe.

Kleinjogg was born in 1716, one of five brothers, in a country village near Zürich (Wermatswil). There seems to be little in the externals of his life that could call forth worldwide recognition. With a brother he took charge of his father's heavily mortgaged farm and, contrary to expectations, made it prosper. Later he took over the management of another farm in the immediate vicinity of the city—the Katzenrütihof. He devoted his entire life to his farming operations and to his large family.

He never left the confines of his native place. He never thought of writing books and indeed was in no position to do so. His life was modest in the extreme. He was a peasant, not a free man, and subject to the guild regulations of the city. He died in 1785 on his own soil and left the farm to his children.

This modest, plain Zürich farmer had already in his lifetime won international respect. His fame began when a Zürich doctor (Hans Kaspar Hirzel, born 1725) learned to know and love him. Hirzel wrote books about his life and work which were translated into French and became known in many lands. Following upon this the intellectuals of Zürich and of the whole of Switzerland took an intense interest in him. Heinrich Pestalozzi was influenced by him and asked for his advice. Johann Jakob Lavater wrote of his impression upon meeting Kleinjogg: "It was as if a dim vision of humanity already present in my soul was to be lighted up! . . . Silently my soul expanded! A sweet glimpse of unspoiled humanity stood before me."

Kleinjogg's fame went far beyond the boundaries of Switzerland. Goethe visited him on the twelfth of June, 1775. Afterwards in a letter he called Kleinjogg "one of the most magnificent creations this earth has brought forth." Similar praise was given him by many who visited him, including high nobility. Others who knew him only at second hand were also inspired by him, including Jean Jacques Rousseau and Mirabeau, the French Tribune of the People.

In what did the fame of this simple man consist? One might assume that he had by chance become a symbol of the almost fanatical devotion to nature characteristic of the time, an embodiment perhaps of Rousseau's ideal of simplicity. Certainly it may have been a preliminary condition of his fame that life close to nature was being idealised. But Kleinjogg could not have

¹ Translated by Miss Bowers and Miss E. E. Winters, Baltimore, Md.

² Director, Psychiatric University Clinic Burghölzli, Zürich (Switzerland).

become famous without great personal merits.

First of all he improved the methods then in use of cultivating the land and for this reason he began to become known. He took the lead in crop rotation and better fertilization, lightened heavy soil by mixing it with sand, introduced the growing of potatoes into the Canton of Zürich, and many other things. We need not go into further detail. The chief point is that he did not cling to the ancient customs of his fathers, as did his neighbors who farmed the land without any thought for the best way of doing it. Kleinjogg pondered over his work. And what was more, if he concluded that a course of action was appropriate, he adopted it without hesitation. At that time this was something remarkable, for little initiative was expected from the peasant. He was supposed to follow good old customs and do what the government prescribed. To appeal to his own reason and to have faith in the success of an innovation which he himself had thought out was indeed revolutionary.³

Kleinjogg was able to clothe his efforts in clear language—even though he did not write them down. He won attention through what he said and through his own example. He expressed himself simply and directly—for example, one must “take the shortest way.” He meant by this that if one has seen the way, he must take it, even if it departs from tradition. His hearers came to believe him because they saw the results. In spite of all the gloomy prophecies of the conservatives, he was able to free the farm from debt and to expand his operations. Kleinjogg let sound common sense rule in agriculture.

But not only in agriculture. One must begin “the reform of the farm . . . with the moral reform of its inhabitants.” Early and late Kleinjogg thought of how men could become healthy and happy. His in-

sight anticipated the most important principles of modern mental hygiene. He taught something that today we call teamwork. Progress will come only from working together. Gentry and peasants must collaborate with each other. He taught this, however, not only in words, but let a community spirit govern his daily life. He worked his land in close association with his own and his brother's families. He esteemed each member equally, but gave him work according to his ability. He undertook agricultural experiments for the Natural History Society of Zürich, for the City Fathers.

He said that teaching and exhortation without example were of no avail. Once he took over his neighbor's “lazy” farmhand and was satisfied with his work. The neighbor wanted to know how this was possible. Kleinjogg explained that he allowed the servant to work beside him, and the boy noted his joy in his work. Since the neighbor had avoided and despised the fieldwork which he had given his servant, the boy had become idle through the master's attitude.

Kleinjogg was convinced that life in the family—the bringing up of children by the parents—was the distinctive characteristic of the human species. He emphasized over and over again that children could become happy and skilful adults only through the example of the parents. He held that harmony between the parents was the highest good, and he lived this conviction. His friend Hirzel wrote, “In his household there ruled only one heart and one will.” He kept his children as much as possible with him, in order to influence them. Work in common was to inspire them.

One could talk for hours about Kleinjogg. Hundreds of pages have been written about him. Our interest lies in the relationship to be found between him and Adolf Meyer.

Adolf Meyer's great-grandfather (Martin Meier, 1741-1799) was a teacher in the vicinity of Kleinjogg's farm. His grandfather (Rudolf Meier, 1790-1870) was a contemporary of Kleinjogg's son, who carried on the paternal farm along the same lines as his father. How very closely Kleinjogg's son lived and worked in the sense and spirit of his father comes to us through a contemporary description of a visit to Kleinjogg's farm in the year 1799. This was a year

³ Dr. Hirzel wrote that for a long time Kleinjogg and his family were “hated by everyone.” People said to him: “We foresee nothing good, since you depart in every way from the usages of our pious fathers.” The abuses which Kleinjogg attacked appeared to many “sacred through long usage . . . In this respect he differed greatly from his fellow peasants, for whom traditional ways of doing things were the warp and woof of life.”

of suffering. The country, including the Katzenrütihof, was laid waste by French, Austrian, and Russian troops. A terrible famine reigned. The city visitor wrote of Kleinjogg's son :

I was astonished at the calm which he possessed, and how he cheered his own people and, in the midst of dire misery, maintained a continuous industry, keeping his household in order, although the food was lamentably poor. I was more astonished, however, to see, even before the beginning of winter, his ravaged fields levelled, worked over, sowed, the remaining traces of the desolation blotted out, and everything brought nearer its former condition than anyone expected.

Adolf Meyer's grandfather, Rudolf Meier, a potter, stove-builder, and the local surveyor, in 1829 surveyed the Katzenrütihof, which up to then had been farmed by Kleinjogg's son. (The measuring tape he used is still in the possession of the family.) Then he leased a part of the farm from the state and took over its management. The farm passed later into the possession of one of his sons, that is, an uncle of Adolf Meyer. There followed also a union between the Meier and the Gujer families through the marriage of a cousin of Adolf Meyer's to a grandson of Kleinjogg's. Relatives of Adolf Meyer still own Kleinjogg's former farm and carry it on. Kleinjogg's spiritual inheritance was entrusted to them through family tradition and they hold it in high honor.

In his childhood Adolf Meyer knew his grandfather, who lived so intimately with Kleinjogg's heritage. The ties of Adolf Meyer and his relatives with the Katzenrütihof remained close up to this century. Amongst other things, Adolf Meyer's mother, after she had lost her husband, lived for about two years in the Katzenrütihof (c.1897-1899) and later in the neighborhood.⁴

Given then the physical relationship between Adolf Meyer and the heritage of Kleinjogg, it is also easy to prove intel-

lectual bonds. It was Adolf Meyer's great merit to clear away rigid, progress-hindering traditions in psychiatry. He made possible an unprejudiced and realistic evaluation of mental disturbances by bursting the stiff frames of the old nosology which allowed no fruitful progress in genetic research to emerge. Untroubled by old thought-schemes, Meyer observed in psychiatry what lay before him and drew conclusions from it. With alert eyes and mind he took the shortest way and did in psychiatry what Kleinjogg had done in agriculture. "I was quite astonished to find him free of old prejudices," wrote Hirzel in 1792 about Kleinjogg—and the same thing was written 150 years later by visitors to Adolf Meyer.

Like Kleinjogg Adolf Meyer believed in the plasticity of man. Adolf Meyer brought home to science the importance of the community, of the relationships of men amongst themselves, in the life-development of both the healthy and the sick—as Kleinjogg had done before him. Both great men lived their conviction that one must cultivate human relationships in the family circle in order to advance the evolution of succeeding generations.

It was self-evident to both men, also, that psychology and biology should be viewed with the same eyes and that one supplements the other. Kleinjogg often compared plants, animals, and men as to the conditions of their development.

Kleinjogg's highest goals for mankind corresponded to Adolf Meyer's psychotherapeutic goals, to his high esteem for family life and human interrelations, as well as to those later taught by psychoanalysis. Inner forces struggling against each other should come to adjustment. In order to arrive at this goal, the child must, according to Kleinjogg, grow to maturity through the example of the parent; the patient, according to Meyer, in the atmosphere created by the physician. The assumption on which this rests is the maturity of the father and of the psychotherapist. Of Kleinjogg Lavater said : "Thinking, speaking, and acting were in him always in the greatest harmony." Kleinjogg said to Hirzel: "The true greatness of man lies in a proper balancing of

⁴ I am indebted to the relatives of Adolf Meyer living today, Herr Jakob Meier of the Katzenrütihof and Herr Jakob Meier of Glattbrugg, for the statements concerning the connections of the Meyer family and the Gujer family.

actions with understanding."⁵

Thus we may assume that the "common sense psychiatry" of Adolf Meyer had its spiritual roots in Kleinjogg's "common sense philosophy."

LITERATURE ON KLEINJOGG

A remarkably comprehensive description,

⁵ "Die wahre Grösse des Menschen besteht in einem richtigen Verhältnis der Handlungen mit unseren Einsichten."

out of which the above quotations have been taken, is :

The chief contemporary work about Kleinjogg is :

Johann Kaspar Hirzel : Auserlesene Schriften zur Beförderung der Landwirtschaft. Zürich, 1792.

A WORKING CONCEPT OF MATURITY OF PERSONALITY¹

JOHN C. WHITEHORN²

The psychiatrist does his clinical work in a particularly personal mode. Like other physicians he is concerned with infectious diseases, toxins, metabolic disturbances, congenital anomalies, genetic handicaps, and other relatively impersonal factors or processes which hinder people in coping with life situations, but the psychiatrist has a particularly strong interest in the patient's personal experience of coping, and in the possibilities of helping the patient cope with life with greater effectiveness and with less distress. All physicians, concerned with the health and welfare of their patients, have an interest in restoring their patients' self-confidence and effectiveness, but it is the psychiatrist who has this concern as the central point of his professional task.

Psychiatric patients in general are not coping effectively with their personal life situations. In general, the disability and distress which bring the patient to a psychiatrist are manifestations of some ineffectiveness or disturbance in social functioning. The psychiatric patient, in attempting to cope with his life situation, is characteristically using an unsuitable pattern of reaction—often grossly unsuitable. It is somewhat inaccurate to say "attempting to cope with his life situation," for the patient often is not really coping with life, but only posturing, that is, demonstrating a pattern or attitude which has little or no useful effect in his life situation, but in which he persists. The attentive study of the patient's pattern of reaction, considered in relation to his life situation and personal biography, will often reveal that his current non-useful pattern of behavior has much relevance for some earlier issue in his life, unresolved at that prior time. As a clinician, eager to gain a useful understanding of psychiatric patients and their problems, I have found much help in the concept of "unfinished business." In-

tensive study may reveal that the current life situation, as the patient has been experiencing it, contains for him this older issue; and in this sense his mode of reaction has some relevance, but oblique relevance. To an outsider's common-sense view the patient's behavior or feelings appear quite inappropriate. His behavior is very likely to be misunderstood by those with whom he is reacting, so that he fails to be constructively effective, except as he may gain from others some dependency, protection and care, by reason of his distress and disability. Even the psychiatric expert may have difficulty in understanding the issue, as the patient experiences it.

The repetitive, ineffectual pattern manifested by the psychiatric patient is usually at first observation a puzzling phenomenon. Seeking appropriate words to describe the patient's behavior one may at times find it appropriate to use terms like "childish," or "infantile" or "adolescent." I recall, for example, a middle-aged woman patient, in a morose and gloomy state, who forcefully told me, "I'm no baby. I know what I want, and I want what I want when I want it"; and this statement has seemed to me a beautifully clear-cut expression of an infantile attitude.

Such clinical characterizations of a patient's attitudes as immature have seemed to me at times very apt and very meaningful. They deserve careful study and systematic formulation,—a task which has engaged much of my interest for some years.

There was ready at hand, a few decades ago, when I began to give serious attention to this problem, a beautifully clear and simple formulation of levels of immaturity, set forth by Dr. Sigmund Freud in terms of his theory of libidinal determinism. This was the theory of erogenous zones, and of the fixation of libidinal interest at the oral, the anal, or the genital phase of psychosexual development. But this Freudian formulation seemed to me much oversimplified, and often quite beside the point. The useful meaning about human behavior

¹ A lecture given at Dartmouth Medical School, Hanover, N. H., May 29, 1961.

² Professor Emeritus of Psychiatry, Johns Hopkins University, Baltimore, Md.

which we seek to express when we use words indicative of immaturity is a meaning concerned with attitudes about responsibility and authority, only tangentially related to the libidinal interest with which Freud was so strongly preoccupied. The practically useful meaning of maturity or immaturity is centered, as I see it, on the humanly inescapable problems of leadership, authority and responsibility,—inescapable because man is a domestic and social animal. The domestic and social patterns of living, which constitute the human way of living, contain inherently the problem of leadership. Freud was not altogether wrong, I think, in relating infantile attitudes to the mouth and anus. The experiences of weaning and toilet training are about the earliest impressive experiences of authority and frustration by other human beings. "Unfinished business" in respect to these issues is often encountered in the psychiatrist's work. But the original Freudian formulations here were somewhat misleading in placing all motivational emphasis upon libidinal interests.

In formulating our conceptions of human nature, we of the late nineteenth and early twentieth century have been strongly influenced by the Darwinian revolution. Psychology has become a subdivision of biology,—“psychobiology” as Adolf Meyer called it. Mentation got a functional orientation: perception, cognition, affect and conation were freshly conceived as preparatory aspects of behavior. That was all to the good, in my opinion. But in the early post-Darwinian enthusiasm for biologizing human nature, excesses occurred. Particularly were instinct theories pushed to disproportionate extremes. Freud based his formulations of personality development upon the sexual instinct, on the basis of certain clinical observations and inferences. Yet, instinct is but a fragment in the life of man. In regard to instinctive endowment man is far surpassed by many animal species. Each human being is born weak and helpless and survives only by the sufferance and sympathy of others, enduring a long period of helplessness and inadequacy, indeed an unending dependency. Human beings, we may truly say, never do become wholly mature and independent, in

the sense in which we might describe some animals in their adult stage as mature and independent. Human beings achieve such a state as we usually call maturity only by developing a good working accommodation to the inescapable fact of their inevitable interdependence.

Let me recite just a few of the items illustrative of persisting human immaturity: The adult human remains childishly curious and distractible; he is readily provoked to laughter; he seeks playful activity, sometimes at great cost; he does not develop fully the specialized capacities which distinguish his more maturely developed anthropoid cousins and which enable them, biologically, to live more independent lives. In comparative analogies, man is a weakling baboon, an incompetent chimpanzee, an awkward monkey. He does not even grow an adequate coat of hair.

The Dutch anatomist Ludwig Bolk accumulated an impressive body of evidence that the human adult resembles in many anatomical details the foetal state of his anthropoid ancestors or cousins. Bolk's observations prompted a foetal theory of the origin of man, namely, that man is a creature of ape-like origin who couldn't reach maturity but was condemned, so to speak, by genetic mutations to suffer a suppression of his previously more adequate ape-like biological potentialities. By this theory, the effects of suppressor genes have kept man in some respects, and to some degree, in a permanently foetal or infantile condition, compared to his immediate predecessors and the other anthropoids who took a different line of genetic development.

I make use of this theory to suggest that there may be a very sound reason why in the discussion of maturity and immaturity we are often embarrassed by our inability to give a wholly satisfactory definition of what we mean by maturity. As I have said, maturity in human life is an ideal rather than an actuality,—something toward which we struggle but do not quite reach. At any rate, maturity is never a gift which comes to one like a trust fund upon reaching a specified birthday. Whatever approximation to maturity one may attain is attained through conduct and behavior, not by merely waiting for the maturation of

instinctive endowment.

At the level of responsible human performance, human behavior and its motivation can be more adequately and reliably understood in terms of attitudes rather than of instincts,—attitudes developed through social experience in a milieu characterized not merely by censorious and authoritarian controls but also by gregarious and protective tendencies. Thus, attitudes, socially cultivated, have much greater significance for social-emotional value and for practical effectiveness in human living than any human instinctive endowment.

Conceptually, for the professional student of human behavior, concerned to establish sound observational supports for his motivational inferences, the term "attitude" has a further value. It provides a more directly verifiable meaning for working with actual human beings than is provided by the concept of instincts. Instinct concepts, when utilized for the understanding of human behavior, are rather remote abstractions from the observable realities of human beings in action; such abstractions have for some workers the attractiveness of apparent depth and ultimate verity. Attitude concepts give one a somewhat less gratifying feeling of grasping the ultimate, but give a compensating sense of observational reliability because attitudes are more directly discernible than instincts, while at the same time attitudinal characterizations leave open the possibility for those who are so disposed to make further inferential leaps toward instinct formulations, if and when justifiable.

CHARACTERIZATIONS OF IMMATURE ATTITUDES AND IMMATURE LEVELS OF PERSONALITY DEVELOPMENT

Having presented, sketchily, a biosocial frame of reference, I shall now go back to the clinical descriptive work and present briefly a 4-stage scheme for characterizing immature levels of personality functioning, which I have designated for obvious reasons as the infantile level, the childish level, the early adolescent level, and the late adolescent level.

Infantile level. At the infantile level one expects from others a limitless amount of service and consideration, without feeling

any reciprocal obligation.

Childish Level. At the childish level there has developed some sense of responsibility, but of delegated responsibility, the kind that is completely erased by a good excuse. The alibi habit is a characteristic manifestation of this stage. Great circumstantiality of speech is a useful clinical clue. Persons at the childish level expect complete reliability in others but only formal effort, up to the excuse level, in themselves. They may expend more effort in framing acceptable excuses than might be required to get a job done. Obsessiveness as a substitute way of establishing merit is rather characteristic of this level. Praise or blame is the focus of attention.

Early Adolescent Level. At the early adolescent level exhibitionism and prestige-seeking are the outstanding manifestations. There is a strong push to assert one's personal significance, and to sustain it by repetitive demonstrations. Badges and trophies have high value as demonstrable symbols of prestige. The striving for self-importance requires extra-familial supports and these are characteristically found in idealistic hero-worship and in gangs.

Late Adolescent Level. The late adolescent level is the stage of "isms,"—romanticism, idealism, or cynicism, for example. The sense of social responsibility has become more generalized in the form of loyalty to a cause, as well as to a hero or a gang. The tendency to excess is still present, as in early adolescence, but it is doctrinaire excess rather than strenuous physical excess. The pseudo-sophisticated "line" of talk, the "wisecrack" and the sophomoric savant are easily recognizable manifestations. Sexual interests are expressed in pairing off and in courtship behavior, but success in this field, or the anticipation of success, may have the emotional quality of a conquest rather than of mutual devotion.

CAUTION

Now, I should add a few words of caution in the use of these schematic propositions. First, they are highly schematic. Secondly, I have found by experience that young physicians, learning to study their patients from this point of view, tend to

slip into the use of these terms as epithets, in effect accusing the patient of being infantile, or childish, or adolescent. The real purpose of these concepts is not to place blame, but to help one appreciate the patient's attitudes, for the better understanding of his distress or disability. The physician can be aided to get a more constructive value from these characterizations of immaturity by considering them in relation to human emotional needs.

THREE EMOTIONAL NEEDS

I have found it helpful, therefore, to relate the levels of immaturity to three emotional needs, 1. The need for affection; 2. The need for personal security; and 3. The need for personal significance. I have characterized them as *needs* because it appears to me that a person has to have some satisfaction in these three respects in order to develop and maintain the social assurance required for effective participation with others. The three form a series having relatively different degrees of importance at different stages of personality development. All three needs exist at all stages but the emphasis is different at different stages.

The Need for Affection. The predominant emotional need in infancy is the need for affection. Affection assures protection, care and nourishment; but affection means more. It fosters enthusiastic mutual responsiveness and attitudes of eager expectation in the most elementary social situation of parent and child. Affection provides some assurance of favoritism at a time of great dependency when some special favoritism is greatly needed. In some persons the infantile pattern of dependency upon affectionate favoritism persists far beyond infancy. One may say that such a person has clung to infantile values, or has been fixated at such levels through extreme attachment, but it is my impression that the principal reason for such an extreme block in development lies in the failure of the home to provide the sense of personal security needed to negotiate the next step.

The Need for Personal Security. In order to participate with comfort in the competitive life among other children, or even to endure without extreme distress the uncertainty aroused by parental absence, little

children need to gain from their experiences a reasonable expectation that the universe is dependable. If mother has to leave, mother does come back; food is forthcoming at suitable intervals, and so is affectionate attention.

Later, the custom of sharing goodies, and the custom of taking turns, inculcate a faith that fair play characterizes the operations of the youngster's universe. This faith is supported and strengthened by the interventions of parental figures supporting principles of fair play. Without the faith built on such experiences one feels very much in danger, not only from aggressive attacks, but from one's own tendencies to aggression, which might elicit overwhelming retaliation.

Lack of support or lack of firmness in parental figures endangers this security; frequent and unpredictable conflicts between parents wreck it; favoritism and overprotectiveness from parents inhibit its development. The reasonable expectation of fair play is one of the conditions necessary for a person's eager exploration and adventure in the give-and-take of social living,—not a guarantee of absolute justice, but just a reasonable expectation of fair play. Fair play is a good bargain for all concerned, and most youngsters appear to perceive that it involves obligations to adhere to fair practices oneself.

The psychiatrist not infrequently encounters patients whose faith in fair play or whose sense of security has gained so little validation from experience that they have had to rely throughout life upon favoritism in the infantile pattern. Lacking the sense of security that comes from a faith in fair play, some infantile personalities live life timidly and with great circumspection. Other infantile personalities, with careless abandon, dare foolish risks and impulsive adventures, apparently as means to gain repeated manifestations of the protector's favoritism and power. I have seen such examples in which it appeared that the protector took a childish delight in the extreme expression of favoritism and indulgence, and I have been tempted to label this partnership *infantilism a deux*.

The childhood phase of personality growth, with the emphasis upon the de-

velopment of personal security, covers a good many years and a large experience of role-enactment, whereby the boundaries of social tolerance or social approval may be fairly widely explored.

The Need for Personal Significance. The widest extravagances in testing the limits of social tolerance are likely to appear in adolescence. In the usual course of events in our culture, one feels in adolescence an increased need to assert one's personal significance, sometimes very brashly against authority figures such as parents, sometimes in exhibitionistic physical exploits, and often in late adolescence in a rather exaggerated radicalism or excessive reactive conservatism.

We are also familiar in our culture, perhaps more so than in other cultures, with the grown-up, middle-aged adolescent,—grasping at opportunities for self-display, insatiable in the pursuit of badges of distinction, chasing after sexual exploits or other types of mastery, dramatizing attitudes of impudence or contempt of propriety.

In psychiatric case material one can find abundant evidence that difficulties of adjustment and psychopathological states often involve motivations based upon extreme needs to assert personal significance. The self-assertive behavior prompted by such needs may be quite annoying. As a clinician and a therapist, I do wish, however, to put in some good words for these adolescent motivations. Behavior thereby motivated may be exasperating, but the patients who manifest it do get well, pretty regularly. Such motivations may prove very useful at certain stages of psychotherapeutic strategy.

TOWARD A MATURE PERSONALITY

Up to this point we have been concerned mostly with immaturity. Now we should consider maturity. Complete maturity is an ideal, only approximated in reality. In what we call the mature personality a manageable flexibility of social attitudes has been achieved. This is manifested in a variety of role behaviors, developed through life experiences which have served to fulfill emotional needs reasonably well.

The mature individual has not graduated

to a stage in which he no longer has these needs; rather he has attained flexibility in accepting and acting out the roles which satisfy these emotional needs. In developing his personal accommodation to the basic condition of human life—interdependence—he has had gratifying experiences of leadership and of loyalty, of domination and of submission.

To get along with other people who are in varying stages of maturity a person needs to maintain the capacity for playful good humor. He can, on appropriate occasions, quit being soberly grown-up and enter into adolescent and childish activities with spontaneity and gusto. He can share with lively sympathy in the emotional values pertaining to those less mature levels of social development. He can not only enter into immature emotional contexts, but he can come out of them again, as occasion requires, and resume more responsible roles, also with good humor and with some measure of playful enthusiasm. Indeed, it might be said that the mature person, in order to maintain the emotional attitudes required by the fact of persisting interdependence and to handle the friction generated by such interdependence, has to retain and exercise some propensities for childish playful curiosity and amusement.

CLINICAL USEFULNESS OF THESE CONCEPTS

I would find myself much handicapped in my professional work without some appreciation of the human being's need for affection, for personal security, and for personal significance, and without some means of recognizing levels of immaturity which characterize persons who have suffered critical deprivation of these needs. I would lack understanding of many patients whose anxieties and frustrations are not readily appreciated when viewed from an adult, common-sense point of view, but whose problems become understandable when one appreciates the immaturity of their personal development and the extent to which their sense of well-being is dependent upon the preservation of social contexts suited to immature levels. In such a frame of reference one can also understand better a person's temporary regression to earlier levels of immaturity in the face

of frustrating and intolerable life situations.

HOW MUCH FREE CHOICE?

Having spoken now at some length about the environmental deprivations which may seriously limit the development of mature attitudes, I should now try to balance the discussion by some reference to a person's role in his own development. It happens that I am not one of those who believe in complete, 100%, determinism. To a small extent, but to a significant extent, human beings, as I see them, seem able to exercise some degree of choice in behavior.

According to the foetal theory of the origin of the human species, suppressive genetic mutations made man enduringly immature, as compared to the chimpanzee, and prevented him from developing the fully specialized repertoire of his Simian cousins. We may be handicapped by such deficiencies, but we have gained a degree of freedom in modifying our behavior. We have gained some chance of escape from the coercive force of instinctive patterns of life, and we have developed patterns of domestication and socialization which permit a certain degree of freedom of personal preference or choice.

It is indeed one of the significant achievements of civilization to have gained for so many an enlargement of their individual freedom of choice of behavior. The rules

required by the social nature of human living are not too highly restrictive. Some leeway exists so that individuals may give acceptable expression to their temperamental differences, and thus participate with gratification and enthusiasm within the broad bounds required by their mutual interdependence.

Unfortunately, many people feel, unnecessarily, that they are oppressed or deprived, and fail therefore to develop their opportunities and employ their capacities. This is particularly true of the psychiatrist's patients. The basic psychotherapeutic task can be distinguished from merely comforting manoeuvres, or merely supportive, or corrective, or interpretative techniques. The basic psychotherapeutic task consists essentially in awakening a person to the more enthusiastic and spontaneous exploration of his available degrees of freedom, and in eliciting hopeful and constructive efforts along lines of his interest and competence. The potentialities thus evoked encourage the patient to cope more effectively with his life situation and may even lead to greater maturity and achievement than previous to his illness. It is one of the greatest gratifications to the psychiatrist when he is able to evoke in an immature patient the faith and enthusiasm and effort by which he achieves a more advanced level of personal growth.

COMPARATIVE ANALYSIS OF THE ACTION OF BUTYRYPERAZINE AT MANHATTAN STATE HOSPITAL AND THE UNIVERSITY PSYCHIATRIC CLINIC AT ERLANGEN

HERMAN C. B. DENBER, M.D.,¹ D. BENTE, M.D.,² AND PAUL RAJOTTE, M.D.³

A discrepancy between the clinical findings in this hospital and the University of Erlangen following treatment with butyrylperazine has stimulated a comparative analysis of the data(1, 2). While the literature on clinical evaluation of drugs grows each year, there has been a striking dissimilarity in reports of trials with the same drugs. A tacit assumption has been that all things being equal, the drug constituted the only variable. Nevertheless, emphasis has been placed recently on two areas which can potentially influence the final results of drug trials—(a) differences in the setting(3, 4), and (b) particular attributes of the investigator(5, 6).

It has been assumed that if the disease treated (schizophrenia), was the same in different parts of the world(7, 8), then the favorable effects of drugs upon the various symptoms should be susceptible to reduplication. This has been true with some of the older and a few of the new compounds. Others have yielded excellent results in some countries(9), but poor to mediocre results elsewhere(10).

Butyrylperazine was synthesized by Horlein, while Wirth, and his collaborators did the pharmacological investigations(11). Flugel, *et al.*(12), have reported on their clinical trials of this and different congeners, finding that the butyryl derivative was most potent. Studies of the same drug, secured from the Farbenfabriken Bayer, Leverkusen, in the research ward under conditions standardized since 1957 could not duplicate the German findings(2). A review and comparison of our material indicated clearly that there were important differences in both groups that required

further investigations.

Twenty acute and chronic female psychotic patients were studied at Manhattan (ranging in age from 18 to 53 years), while in Erlangen there were 26 patients with an age range from 17 to 54 years (Table 1).

¹ Director of Psychiatric Research, Research Division, Manhattan State Hospital, Ward's Island, New York 35, N. Y.

² Oberarzt, Universitäts-Nervenklinik, Erlangen, West Germany.

³ Associate Research Scientist, Research Division, Manhattan State Hospital, Ward's Island, New York 35, N. Y.

There were 2 manic-depressive patients in the Manhattan group, while the remainder in both was schizophrenic. The onset of illness and number of previous hospitalizations were similar for both groups. The social classes were lower middle or low (Table 2). The parents of the Manhattan patients showed a heterogeneous national origin, as compared with the Erlangen group (Table 3). Sixteen of the Manhattan patients were born in the United States, while in the Erlangen group all patients were of German origin.

The drugs were administered *per os*, although at Manhattan the intramuscular route was used the first 1-5 days in 17 patients (Table 4).

TABLE 4

90 mg. oral		

The patients were either recent admissions or chronically ill who had not responded to prior medication.

RESULTS

The duration of treatment was similar in both groups. The final daily dose varied considerably between the 2 groups (Table 5), with a daily average dose at Erlangen of 26 mg., and 126 mg.⁴ at Manhattan.

The extrapyramidal reaction occurred 18 times in 26 patients (Erlangen), but only in 8 of 20 patients at Manhattan. There were no dyskinetic reactions in the latter

⁴ Average based on 19 patients.

group, but this was noted in 11 of the German patients.

The therapeutic effects were mediocre at Manhattan, but excellent in Erlangen (Table 6).

TABLE 6
Results

	MANHATTAN	ERLANGEN
Much improved	4	18
Improved	4	7
Unchanged	11	1
Worse	1	0

The drug did not produce much listlessness or apathy in either setting. The number of side effects was minimal. There were no blood dyscrasias or evidence of hepatic abnormalities.

DISCUSSION

It would appear that the striking dissimilarities in findings should have some basis (biological, social or biosocial) which have either been unsuspected or ignored before in similar situations. The diagnostic groupings were eliminated from consideration, since they were similar and criteria for diagnoses were the same. The age and duration of illness before admission were subjected to statistical analysis, and no significant differences were found between the groups.

There was a disparity in social class (Table 2), made all the more important by differences in social structure between the United States and Europe. It is fairly certain that the Erlangen lower class would be considered here as being in the lower echelons of the middle class. It would be difficult to find an equivalent group for the New York lower class in the area served by the Erlangen Psychiatric Clinic.

The differences in initial dosage schedules were a factor of experimental design, since the research technique at Manhattan often uses the intramuscular route for the first 2-5 days to achieve rapid control.⁵ However, better than half of the Manhattan group finally received 90 mg. or more daily, while 17 of the Erlangen group received 20 mg. or less (Table 4). Theoretically, these relatively high doses should have produced an inordinate number of extrapyramidal reactions in the Manhattan group. Actually, the reverse was true. At Erlangen, an extrapyramidal reaction was noted at 15-20 mg. daily. Three of the 4 Manhattan patients who received 300 mg. daily developed the extrapyramidal reaction. The daily dosage of the other 5 patients was 30, 90, 150, 160, and 270 mg., respectively.

Dystonic reactions tend to occur in the younger age group receiving psychotropic drugs. Yet this was noted in 42.3% of the Erlangen patients with an age range of 17-52 years, and a mean of 35.6 years, and not at all at Manhattan where the age range was 18-56 years with a mean of 39 years. It is conceivable that these reactions may in some way be related to the route of administration.

The results were mediocre at Manhattan with 8 of 20 patients showing improvement, while the greater majority of the Erlangen group was improved. Certainly it could not be said that this was a factor of either dose or period of treatment, since the doses of the Manhattan group were the highest, with the period of treatment approximately the same for both. The type of patient treated, in terms of chronicity and diagnoses, was approximately the same. The problem of criteria for change will have

⁵ We recognize this concept to be open to question.

to be considered in future studies, since this is essential in the comparison of results. Nevertheless, the biologic responses must still be explained.

It is of interest to note that the Erlangen group was composed of about equal numbers of patients born in Franconia (the area in which the hospital is situated) and those provinces now belonging to Czechoslovakia and Poland. There were some differences in results between both groups, but the smallness of the sample did not allow any statistical validation.

The data are suggestive but far from conclusive regarding the contributory role of social factors to the observed differences. Eventually, the differences in social class might be indicative of a household more receptive to the patient's return home. However, our data refer only to in-hospital improvement. It is conceivable that methodologic differences could have played a role in producing such biological results. Different settings, physicians, and staff, as well as different technical approaches, can be implicated. It is difficult to see how methodology can produce such differences in biologic reactivity (Tables 4 and 5). It can be argued that since chlorpromazine and other drugs gave similar results in both continents, the dissimilarity with butyrylperazine is indicative of a different therapeutic technique. Our comparative observations give no substance to support such a proposal. It is known that some drugs have given the same results (chlorpromazine, prochlorperazine and imipramine), while others have not (haloperidol and Taractan). We believe it possible to learn more about drug action by an analysis of these differences.

It could be assumed that the dose requirements and neurologic reactions are the sum total of the individual's genetic constitution, and the responses to environmental influences (chemical, physiological or social). Biologic reactivity results from the summation of organic responses, in themselves the result of gene direction and interaction with the environment. Any strong differences between groups would implicate either (a) different modes of biological reactivity which in some cases may be based on learned environmental factors, (b)

treatment resistance resulting from fusion of genetically heterogeneous groups, or (c) different rates of metabolism of the drug which may well be under genetic control.

If the foregoing hypotheses are acceptable, then it can be reasoned further that differences in organ responses to a standard condition (here it is the administration of butyrylperazine) can be accounted for by either genetic control, environmental influences, or both. Other than the social class differences, there are no apparently strong environmental factors that seem to have been operating. The only differentiating factors between these two very similar groups were the dosage requirements, the side effects and the clinical results.

We, therefore, hypothesize that the difference in response was a function of the genetic information available to each group.

SUMMARY

1. Butyrylperazine was administered to 20 patients at Manhattan State Hospital, New York City, and 26 patients at the University Psychiatric Clinic of Erlangen, West Germany.

2. There were significant differences between both groups in (a) dosage requirements, (b) side effects, and (c) clinical results.

3. It is suggested that genetic factors may play some role in explaining at least two of these findings (2a and b).

DIAGNOSTIC CONSISTENCY IN A PSYCHIATRIC LIAISON SERVICE

MURRAY S WILSON, M.D.,¹ AND EUGENE MEYER, M.D.²

Diagnosis in terms of standard nomenclature has not enjoyed much esteem during the past two decades among American psychiatrists. Partly they have been in revolt against the tendency Kant caricatured when he wrote that doctors believe they have done quite enough for their patients if they have given their disease a name(1). Patterson(2) pointed out in 1948 that a diagnosis was not a prerequisite for treatment. Another factor was that terms such as schizophrenia, or depression gave relatively little information about a patient's specific intrapsychic turmoil. Unfortunately their successors, hostile-dependent, or castration fear, which have come to be so glibly used, are little better in that regard, and defy meaningful classification because of their inherent complexity. Masserman (3, 4) among others, has fostered the shift in emphasis to conceiving the patient in terms of motivations and dynamics, denigrating diagnosis. But the recent appearance of epidemiological studies in psychiatry, relying as they do on some form of readily classifiable nosology, demands a reassessment of our psychiatric nomenclature. There have been few studies even of consensus in the use of terms.

In the psychiatric liaison service of The Johns Hopkins Hospital the most prominent gross feature of a patient's usually multifaceted psychiatric illness is used for the purpose of cataloguing cases. We observed a high degree of concordance in the diagnoses assigned by the service during two successive years.

Our data were collected on four public medical wards of the hospital that were in continuous operation throughout the 2-year period. In each instance the attending medical interne referred the case to us, and every case for whom the consultation request was answered is included; a few patients either died or were discharged be-

fore being seen. The setting has been elsewhere described at length by Meyer and Mendelson(8).

During the first year of the study (July 1, 1957-June 30, 1958) 5 psychiatrists saw 128 patients of a total ward population of 2,164. Several patients were given more than one diagnosis, *e.g.*, 1. Acute brain syndrome due to barbiturate intoxication, and 2. Psychoneurotic reaction, depressive reaction. In all, 150 diagnoses were made in this year. Four psychiatrists saw about an equal number of patients; one saw only 3. During the second year (July 1, 1958-June 30, 1959) 166 patients of a total ward population of 2,438 patients were referred for consultation. One-hundred eighty diagnoses were made by one psychiatrist(M.S.W.), who had not previously worked as consultant on these wards and had no knowledge of the diagnoses assigned during the previous year. All psychiatrists used the diagnostic reference manual authorized by the American Psychiatric Association in 1950, familiarly known as the "gray book." (We have, however, here deviated in grouping all depressions together. It is often difficult to decide in a relatively short time whether a patient should be called psychotic. Communication is usually poor, and elements of both psychotic and non-psychotic thinking and behavior seem to co-exist.)

The slight increase in the total ward population in 1958-59 was distributed among both sexes and races with a slight preference for Negro men in early middle years. Possibly the higher rate of referral in the second year was due to the psychiatrist's frequent attendance at medical rounds; thus he was asked to see more cases than he would have otherwise.

Table 1 presents the expanded form of the results. In Table 2 the groups are compressed to show more clearly similarities and differences. The total number of diagnoses was used as denominator in calculating percentages.

Psychoneurosis (excluding depression)	13%	16%
Personality disorder	25%	19%
Other	7%	5%
No diagnosis	9%	10%

% Given of total diagnosis.

There is very little difference in the proportionate distribution of psychiatric illness between the years.

DISCUSSION

The ideal measure of consistency among psychiatrists in the use of diagnostic terms would be to have several psychiatrists evaluate the same cases. Ash(5) reported on this method in 1949. He found that 2 psychiatrists agreed on the major category in about 60% of cases; agreement between 3 psychiatrists occurred in 45%. Rosenzweig, *et al.*(6), found that with patients in a state hospital who had been there for 2 years, 2 psychiatrists familiar with the hos-

pital agreed on diagnosis 96% of the time. Vera Norris(7) compared the diagnoses assigned in an observation unit with those subsequently given in the mental hospital. She found an overall concordance of about 60%.

In our series we have only similarities. The patient population was drawn from the same section of Baltimore during the 2 successive years. It was admitted to hospital by the same process of selection each year and referred for psychiatric opinion when necessary under the same hierarchical arrangement among the house-staff. Each year, however, it was a different patient

population and a different house-staff. In the first year the diagnoses were assigned by 5 psychiatrists, all of whom had had some of their training at the Henry Phipps Clinic, while in the second year they were assigned by one psychiatrist who had been trained in the same geographic area, but at different places than his colleagues.

We conclude that in a large ward population, drawn annually from the same segment of a city, and admitted to hospital under the same criteria, a consistent rate of different psychiatric conditions occurred; these were diagnosed highly consistently by different psychiatrists of approximately equal training.

It seems hardly necessary to emphasize that the concepts of mental illness are developing and changing; nonetheless, it is an item of importance if, in existing diagnostic terms and current concepts, diagnoses can be made with consistency. Epidemiological studies, for example, require such consistency. We believe our findings confirm the value of diagnoses for use in this way.

SUMMARY

This report suggests that there are gross constellations of mental disorder psychiatrists routinely identify with consistency, using the current standard psychiatric nomenclature. Striking similarity in the frequency with which diagnostic categories occurred during two successive years in a psychiatric liaison service are cited as evidence.

RELIABILITY OF PSYCHIATRIC DIAGNOSES :

1. A CRITIQUE OF SYSTEMATIC STUDIES ¹

AARON T. BECK, M.D.²

The attitude of psychiatrists regarding the reliability of psychiatric diagnosis is characterized by two opposing trends. On the one hand, the wide diversity of articles about specific nosological categories attests to the implicit acceptance of the diagnostic classifications; these articles range in content from individual case reports to large scale pharmacological, psychological, and physiological studies. In these studies, the diagnostic categorizations form an integral part of the generalizations drawn by the authors. In contrast, a growing number of writers have expressed disillusionment with or frank distaste for the current system of classifying psychiatric patients (4, 9, 16, 21). Some have proceeded to the point of denying the justification for the continued use of certain time-honored, nosological categories such as schizophrenia (4). The general attitude of discouragement is epitomized by the statement of Pasamanick and his co-workers: "Psychiatric diagnosis at present is so unreliable as to merit very serious question when classifying, studying, and treating patients' behavior and outcomes" (16). Such opinions certainly warrant a serious scrutiny of the evidence on which they are based and further systematic studies to determine whether the present system of diagnosis needs to be revised.

DEFINITION OF "RELIABILITY OF DIAGNOSIS"

In assessing the diagnostic system it is important to distinguish between those properties related primarily to validity and those aspects concerned with reliability. The validity essentially refers to the accuracy with which the classifications define behavioral entities. The reliability, on the other hand, represents the degree to which

the same category is chosen upon repetition of the diagnostic procedure.

When the reliability of the diagnostic system is considered, it is important for purposes of clarity to specify which component of the system is being evaluated: the nosology, the diagnostic technique, or the diagnostician. The reliability of the nosology may be considered from two standpoints. The first is its constancy or "temporal reliability" (analogous to test-retest reliability). This characteristic is expressed by the degree of regularity with which the same diagnostic label will apply to a given patient at different points in his illness. This does not assume that the manifestations of the illness remain constant but, on the contrary, that the same diagnostic label will still be applicable despite changes in the clinical condition of the patient. The second index of the reliability of the nosology is the degree to which it facilitates the selection of the same diagnostic label for a given patient by different diagnosticians. A nomenclature which is constructed so as to permit only a low level of agreement even between highly trained and skilled diagnosticians would be judged to have a low level of reliability.

Similarly, in determining the reliability of particular diagnostic techniques (for example, the mental status examination, history-taking or projective tests), it is essential to ascertain the constancy of the derived results when the technique is repeated after a lapse of time as well as the consistency with which the instrument will yield the same results when used by different diagnosticians. The third component of the diagnostic system *viz.* the diagnosticians, may be evaluated in a similar fashion in terms of the consistency and variability of their observations and of their interpretation of the clinical material. The basic data for this appraisal are obtained by having periodic appraisals by the same diagnosticians in addition to separate appraisals by different diagnosticians.

¹ This study was supported by Research Grant M3358 from the National Institute of Mental Health.

² Dept. of Psychiatry, University of Pennsylvania and the Philadelphia General Hospital.

REVIEW OF SYSTEMATIC STUDIES OF RELIABILITY

In view of the acknowledged importance of diagnosis for research, treatment, and teaching, the previous systematic studies of the reliability of psychiatric diagnosis are deserving of close methodological analysis. In a few of the summaries presented below, the data reported by the authors have been reanalyzed to facilitate comparisons between studies and to delineate the salient findings. For example, in series where the proportion of organic cases is high, the consistently high rate of agreement (80%-90%) on these conditions tends to mask the relatively low rate of concordance for the "functional" psychoses, psychoneuroses, and personality disorders. Where feasible, therefore, the overall rates of agreement will be presented with the organic cases excluded. Only those articles are summarized which bear directly on the question of the reliability of diagnoses and which were adequately enough designed to clarify this question.

Masserman and Carmichael(13) followed 100 patients after they left a mental hospital. It was found in 40% of the cases that the diagnoses required "major revision" one year after discharge. This study has been quoted frequently as evidence of the unreliability of psychiatric diagnoses. However, since it is apparent from the authors' description that the changes in the diagnoses were justified by changes in the patients' clinical picture, this finding does not in itself discredit the original diagnostic classifications. However, it does raise the question of the temporal reliability of the nomenclature.

Ash(1) studied the diagnostic classification of 52 white male patients who were seen at a psychiatric clinic associated with a governmental agency. Three psychiatrists participated in this study and the conference method was used, with each psychiatrist asking whatever questions he wanted. The overall agreement between paired diagnosticians for the specific syndromes was 32% and for the major divisions (psychosis, neurosis, and character disorders) 64%. The limitations of this study are: the relatively small number of cases did not allow for comparative data on a wide range of

clinical syndromes; the conference method favored agreement through the inevitable communication of ideas; the nomenclature used in the study contained many vague entities, such as "primitive type," "shiftless, lazy, unethical type," and "reaction to inferiority"; and finally, the categories in the nomenclature were not mutually exclusive.

Mehlman(14) studied the frequency distribution of diagnoses of 4,036 patients at a state hospital. He found a statistically significant difference in the frequencies with which the various labels were used by the individual psychiatrists in categorizing the patients assigned to them. A similar study by Pasamanick, *et al.*(16), showed essentially the same results. Although these studies demonstrate that the psychiatrists had definite preferences in the selection of diagnostic categories, the use of an indirect method did not allow for comparisons of judgments of different psychiatrists seeing the same patient. While there is significance in the demonstration of variability among psychiatrists which is a function of individual diagnostic predilection, this finding does not indicate the degree of disagreement, which would be more relevant to an evaluation of the reliability.

Hunt, Wittson, and Hunt(11) examined the consistency of psychiatric diagnoses in a group of 794 naval enlisted men seen by the psychiatric unit at a naval precommissioning installation and transferred to a naval hospital for medical survey and separation from the service. The diagnoses at the precommissioning station were compared with those at the hospital. It was found that the overall agreement on specific diagnoses was 32%, while agreement on the broad categories (psychosis, psychoneurosis, and personality disorder) was 54%. Some drawbacks of this study are: first, the diagnoses at each installation were based on a study of the clinical record rather than a direct examination of each individual by the physician making the diagnosis; secondly, since the primary function of the diagnoses was to determine suitability or unsuitability for service, administrative considerations (as pointed out by the author) influenced the type of diagnosis rendered; thirdly, since there was a definite time lapse of an unspecified period

between the rendering of the two separate diagnoses, the acute conditions could have resolved during the interval between the diagnostic appraisals and thus could have contributed to a change in diagnosis.

Foulds(7) introduced a novel approach to the problem of assessing concordance between diagnosticians by devising a 6-point scale to indicate the degree of agreement in the diagnoses rendered on an individual case. The scale was based on the idea that pairs of diagnoses which were similar (for example, paranoid state and paranoid schizophrenia) should receive a higher rating than pairs of diagnoses that were totally dissimilar (for example, paranoid schizophrenia and hysteria). When concordance was measured according to this scale, it was found that the degree of agreement on diagnoses between 2 psychiatrists was statistically significant for the 18 patients in the series. However, as the author points out, this scale was lacking in experimental support for the attribution of similarity to the various diagnostic pairs and for the particular weights assigned in the scoring system.

Schmidt and Fonda(19) conducted a study of 426 patients in a state hospital. The initial diagnosis was made by 1 of a group of 8 psychiatric residents during the patient's first week in the hospital. The second diagnosis was made by 1 of a group of 3 staff psychiatrists during the patient's third week in the hospital. An analysis of their data, excluding the organic cases, shows an overall rate of agreement of 42% for the specific diagnostic categories. A special feature of this study is that the new (1952) APA nomenclature(20) was used.

Limitations of this study are: first, the comparisons were made between diagnosticians of very different backgrounds, training, and experience. The residents who made the initial diagnoses were from foreign countries, had only minimal psychiatric training, and presumably had varying degrees of difficulty with English. The staff psychiatrists, on the other hand, were board-certified and had considerable experience in psychiatry. Secondly, at the staff conferences where the official diagnoses were made, the staff psychiatrists had

access to considerably more material than had been available to the residents. This included additional information from such sources as the social history, the psychological and neurological examinations, and the notes on the patient's chart.

Wallinga(21) examined the diagnoses of 804 cases admitted to a navy hospital. He found that in 470 (58.5%) cases there was a change in the specific diagnosis in some stage of their illness. Of these 470 cases, 375 had a change from one major category to another major category (for example, from psychosis to neurosis). As in some of the other studies, the diagnostic judgments were not strictly comparable in that there was often a long period of time between the 2 diagnoses, and often there was considerable discrepancy in the training and experience of the various diagnosticians. Moreover, as in many of the other studies, the fact that the second diagnostician had access to the original diagnosis could have influenced his diagnostic appraisal.

Norris(15) reviewed the diagnoses of 6,263 patients who were diagnosed by psychiatrists during a brief stay at an observation unit and were then transferred to a mental institution where they received a second diagnosis by another psychiatrist a few weeks later. She compared the diagnoses at the two institutions and found overall concordance of approximately 60%. However, there was a very substantial representation of the organic psychoses, which had a high concordance (80%) as compared with the psychoneuroses and the character and behavior disorders, which had a concordance rate of approximately 54% and 43% respectively. Another problem in evaluating the results is that nosological categories of widely differing degrees of refinement and homogeneity were used. Moreover, the overall rate of agreement could have been influenced to an unknown extent by virtue of the fact that the psychiatrists in the receiving hospital knew of the diagnoses made in the observation unit.

COMMENT

The foregoing review of the studies on the reliability of diagnosis indicates a number of methodological problems which make it difficult to draw any definite con-

clusions about the reliability of the present nomenclature. Among the factors that could have distorted the degree of agreement are the comparisons of diagnoses of clinicians of greatly varying degrees of training and experience ; use of poorly defined, overlapping categories ; the introduction of administrative and other extraneous considerations in classifying patients ; inequality in the quantity and quality of information available to the diagnosticians ; the long time intervals between diagnostic appraisals ; and lack of provision for independent judgments by the paired diagnosticians.

Another problem in these studies has been the inconsistent application of the hierarchical organization of the nosological categories which is implicit in the traditional "class model" of classification (for further elaboration, see section on recommendations below). As a result, categories which are substantially different in terms of inclusiveness, homogeneity, and refinement, are treated as though they are on the same level of abstraction. For example, in 2 studies the gross, heterogeneous category of neurosis was treated on the same level as the relatively specific and refined category of manic-depressive disorder.

In view of the widely varying designs used in these studies, any comparison of the results among the studies would be forced and difficult to interpret. However, in order to obtain some general idea of the possible range of agreement, the data presented by the authors were reanalyzed (when such a procedure was feasible) to facilitate comparison. In order to make the samples more consistent with each other, it was necessary, for example, to exclude the "organic" cases from the computations. It was found that, for the studies that were analyzed in this way, the agreement on specific diagnoses was as follows : Schmidt and Fonda, 42% (19) ; Wallinga, 41%(21) ; Ash, 32%(1) ; and Hunt, Wittson, and Hunt, 32%(11).

If these results may be accepted as representative of the degree of agreement between diagnosticians, the question naturally arises : what significance does this have in terms of the practical value of the current system of diagnosis ? The fact that, in at least one study(19), the level of agreement was found to be statistically significant does

not, *ipso facto*, establish the usefulness of the system since the percentage agreement may be low and still be statistically significant. It is evident that any appraisal of the value of the system of diagnosis needs to take into account the specific purposes for which the system is to be used.

It would seem that for research purposes a system of classification using the refined categories, which had an interjudge agreement rate of no better than 42%, would be considered inadequate. On the other hand, if one is interested only in the broader categories (such as neurosis and psychosis), where the degree of agreement is substantially higher, then the present system is more acceptable.

When the utility of the present system for the practical purposes of patient care is considered, it might be regarded as self-evident that the clinician would be greatly handicapped by the variability of diagnoses. However, the extent of this handicap is related to the degree to which the psychiatrist depends on the diagnostic label in actual clinical decision-making. It could be argued, for instance, that the psychiatrist is seldom bound exclusively by the actual diagnosis (except, perhaps, in "organic cases") but bases his treatment recommendations on such characteristics as the severity or chronicity of the illness, the degree of impairment of reality testing and social effectiveness, the capacity for insight, and the motivation for help. Under such circumstances, he might simply regard the clinical diagnosis as an additional bit of information (unreliable though it may be) which may support the therapeutic decisions made on the basis of the other factors. In any event, further research on the question of how the psychiatrist makes his therapeutic decisions is certainly warranted.

The high degree of diagnostic variability among clinicians is, incidentally, not a unique property of the specialty of psychiatry. In other branches of medicine, when the physician is forced to rely solely on his own examination of the patient and a large degree of inference is necessary, a noteworthy tendency towards inconsistency may arise. Systematic studies have revealed a low degree of interclinician agreement on the presence of physical signs of emphy-

sema(6), the assessment of the nutritional status of children(5), the evaluation of pathology of tonsils(2), and the eliciting of specific pulmonary symptoms in taking medical histories(3). Furthermore, it has been shown that pairs of radiologists interpreting the same x-rays showed a surprisingly high degree of disagreement(8).

RECOMMENDATIONS FOR FURTHER STUDIES

In view of the already described limitations of the studies of the reliability of psychiatric diagnoses, it is clear that further studies should be designed to solve these methodological problems. It is suggested that future systematic investigations of the reliability of diagnoses follow certain guidelines so that more decisive conclusions can be drawn regarding the reliability of psychiatric diagnoses. The most valuable information would be derived if these studies were conducted within a methodological framework which would allow for the systematic variation (as well as the control) of the important variables.

1. The most recent version of the standard nomenclature(20), which was formulated to improve the weaknesses in older editions and is widely used at present, should be employed. The participating psychiatrists should initially attempt to clarify the obscurities in the nomenclature and reach a consensus on the criteria to be employed. It is important that cognizance be taken of the fundamental hierarchical structure of the standard nomenclature. The class model on which it is based is analogous to the Linnaean model of classification, comprised of class, orders, families, *etc.* The schema used in the standard nomenclature similarly consists of broad generic categories labeled "disorders," which are subdivided into more homogeneous categories, which are (inconsistently) labeled "syndromes," "reactions," or "disturbances." In some cases, these are further subdivided into more discrete "reactions" or "types." It is obvious that a rational application of the nomenclature should require the selection and comparison of diagnoses of the same level of abstraction. In addition, by varying the level at which the diagnosticians select the categories, it would be possible to determine the relative reliability of gross and

refined categories.

2. The psychiatrists responsible for making the diagnoses should have sufficient background and ability to enable them to make a skillful application of the nosology. Furthermore, the amount of training and experience should be roughly equivalent for each of the participants. To determine the effects of training and experience on agreement, experiments using diagnosticians at successive levels of training and experience should be performed.

3. The conditions for making the psychiatric observations should be kept uniform. These conditions include such factors as the physical setting of the interviews, the amount of time allotted, and the amount of ancillary information (such as social history, psychological test reports, nurses' observations). To determine the effects on agreement when sources outside the psychiatric interview are used, the psychiatrist should render a diagnosis first, without the benefit of the ancillary information; and then, after consulting this information, confirm or revise his initial diagnosis.

4. The time interval between successive interviews of a patient present certain problems. On the one hand, a joint interview by the 2 psychiatrists, or consecutive interviews with a minimal time interval, would appear to be desirable to minimize the variability in diagnoses resulting from gross changes in the symptomatology of the patient. On the other hand, it would seem that an important test of the reliability of a nomenclature of diseases is the degree to which the diagnostic labels remain applicable despite changes in the patient's clinical condition. Furthermore, it could be expected that, if a patient is interviewed simultaneously by 2 psychiatrists, there is apt to be a spurious inflation of agreement through the communication of ideas (see Ash's study)(1). This dilemma may be resolved by setting up a series of experiments to determine the degree of agreement under the following conditions: a joint interview by 2 psychiatrists, but with independent selection of the diagnosis; independent interviews with a time interval between interviews of only a few minutes; independent interviews with a time interval of a specified number of days or weeks. Such studies

could yield important information regarding the relative vulnerability of the diagnoses to changes over time, as well as the degree of interpsychiatrist reliability.

5. In view of the possible influence of administrative considerations on the selection of a diagnostic label(9,11), the investigation should be conducted independently of the routine evaluations and clinical decision-making of the institution.

In addition to the specific suggestions listed above in regard to studies of the reliability of psychiatric diagnoses, it is apparent that a good deal of basic research is required to elucidate just how clinicians go about obtaining data and making judgments, and how they differ from each other in this regard. Such studies will have to scrutinize such elements as interviewing techniques, the degree of inference from observations, and the logical processes utilized by the clinician in translating the data into a clinical diagnosis.

A number of studies have been reported which approach these problems; *e.g.*, Rosenzweig, *et al.*(18), in their study of the reliability of the mental status examination, observed that, while the psychiatrists in their study showed a high level agreement when the same clinical data were presented to them, they tended to vary considerably in interviewing techniques. Raines and Rohrer(17) observed that clinicians tended to arrive at different diagnostic judgments on the basis of their own personality patterns. Pasamanick, *et al.*(16), demonstrated definite diagnostic preferences (or biases) which they attributed to differences in the schools of thought represented by the participating psychiatrists. In a recent study of the reasons for diagnostic disagreements, Ward, *et al.*(22), concluded that 37% of the cases of disagreement could be attributed to inconsistencies or errors in the interviewing techniques, while 58% were related to inadequacies of the nomenclature.

Another promising avenue of research lies in experimenting with different models of classification. The traditional class model, which was described above, implies that a given patient has one and only one psychiatric syndrome. The designation of a specific syndrome automatically excludes all others for that patient. The polydimensional

model(12), on the other hand, does not require that the individual syndromes be mutually exclusive, but assumes that more than one syndrome (*e.g.*, anxiety state, depressive state, paranoid state) may be present in a patient at the same time. This model has been used by a number of techniques which retain the classical nosological categories but treat them as co-existent dimensions of personality(10). These techniques are reported to show a much higher degree of interrater reliability than the conventional method of diagnosis, and in addition provide for quantification of the individual dimensions.

It may be expected that further research in the area of the diagnosis will contribute in a substantial way to the goal of specifying the determinants of mental illness and ultimately to developing more effective methods of treatment.

SUMMARY

Pertinent systematic studies of the reliability of psychiatric diagnosis were critically examined. It was pointed out that each of these studies presented certain methodological problems which made their findings inconclusive. An experimental design was presented to meet these problems and thus yield a more informative index of reliability. By systematically varying the important variables, such as the level of experience of the psychiatrists, the time interval between interviews, the use of ancillary information, and the degree of refinement of the nosological categories, it will be possible to determine their effects on reliability.

DEPRESSIVE BREAKDOWN IN WOMEN OF THE WEST HIGHLANDS

MARGARET M. DEWAR, M.B., D.P.M., AND IAIN MacCAMMOND, M.B., D.P.M.¹

In recent years study of the affective disorders has tended to receive less attention than schizophrenia. The work of Kallinan and Schulz on the genetics of the illness is of enormous importance, as is Merrell's work on the inheritance of the disease; but again two of these writers have also made important contributions to the etiology of schizophrenia.

Review of the current literature tended to confirm this contention. In the *Journal of Mental Science* we found, for example, that in the years 1957 to 1959 there were 79 articles on schizophrenia and only 21 on affective disorders. Review of the American journals of psychiatry tended to confirm this finding. We also found that comparatively little work had been done on the incidence of depression in distinctive groups, despite an impressive survey by Stenstedt in Sweden who used a geographical basis for his work and whose results are contrasted with our own below.

In the following survey we set out originally to examine the generally held concept that there is a higher incidence of affective disorder in the population of the West of Scotland than in other comparable areas in the British Isles. We also attempted to analyse the factors responsible. The planning of the survey immediately presented difficulties. In the first place we had to decide whether to use only patients admitted to the hospital as statistical material or whether to include outpatients. We decided to use only inpatients. Secondly we had to decide whether to use a nominological, an inheritance, or a geographical basis. Geography seemed to offer more accuracy on the grounds that a nominological basis would be hopelessly confusing (many Irish names begin with "Mac" and many "Macs" disappeared after the '45!), and that hereditary factors would be too difficult to trace. We felt also that a geographical selection

would have more statistical validity if it were strictly applied and we have therefore confined our selection only to patients domiciled in the counties of Argyll and Bute.

A third difficulty was that the material obtained was too bulky to handle in one reasonably concise paper. We therefore had to confine the survey strictly to the depressive disorders of youth and middle-age in females. Excluded are depressions in females over 65 years, the affective disorders of the puerperium and anxiety states with incidental depressive features. We hope to publish a survey of the material concerning males and other depressive groups at a later date.

The groups considered are therefore: 1. Involutional melancholia; 2. Manic-depressive psychosis of depressive type; and 3. Reactive or exogenous depression.

In making this selection we applied certain criteria. We are aware that in the light of Tait, Harper, and McLatchie's paper (9) some criticism may be levelled at these criteria; nevertheless we felt that they had clinical validity. Criteria used were:

Group 1. The melancholias.

(a) The disorder had occurred for the first time in the involutional period 45 to 65 years.

(b) Psychomotor retardation was not prominent, but agitation was part of the picture.

(c) The previous personality was rigid and overconscientious.

Group 2. The manic-depressive psychoses.

(a) The disorder should occur for the first time at any age.

(b) It was characterised by psychomotor retardation.

(c) There was a history of a cyclothymic personality.

Group 3. The reactive depressions.

(a) It could occur at any age.

(b) There was incontrovertible evidence of response to environmental conditions.

We proceeded with our abstracts in terms of individuals, not admissions. The

¹ Respectively, Asst. Psychiatrist, and Physician Supt., Argyll and Bute Hospital, Lochgilphead, Argyll, Scotland.

average admission rate of depressives is therefore the patient/admission rate, *i.e.*, 1 individual admitted 8 times in 10 years is still 1 admission. The survey was divided into two 5-year groups, because all the patients in the second 5-year group were known personally to both writers; some in the first 5-year group were not. We would emphasise that a patient numbered in the first 5-year group, readmitted during the second 5 years, was *not* included in the latter group.

Maintaining our exclusions, we found that of 585 female individual admissions from the counties of Argyll and Bute between January 1, 1949 and December 31, 1958, there were 119 depressives (20.34%). We found that of 264 individuals admitted during the first 5 years (1949-1953), 55 were depressions (20.83%). In the second 5-year period, from 321 individuals admitted, 64 were depressives (19.93%)—a drop of approximately 1%.

The relative frequency was as follows:

1949-53	
	NO. OF PATIENTS
Involuntional melancholia	21
Manic-depressive psychoses	15
Reactive depression	19
	—
	55
1954-59	
	NO. OF PATIENTS
Involuntional melancholia	29
Manic-depressive psychoses	15
Reactive depression	20
	—
	64

We would like to quote in comparison from the limited references available to us, the following figures:

1. Merrells has stated that the number of "M.D.P." admissions dropped in 1951 from 18% to 10%. These figures are American and we do not know whether the whole affective group is included, but from the context we imagine it to be. If then we contrast with his figures our own statistics for the 10-year period we find that any of our 3 sub-classes approach the level of his total figures (*i.e.*, the extract percentage for our manic-depressive sub-group alone is 5.12%).

2. Again Burkhart has reported 2.6% ad-

mission rate in Schleswig-Holstein(2).

3. Bellnapp and Jaco(1) quote an aggregate figure of 12.8% in the city of Austin, Texas, for affective admissions, and contrast this with 10.4% for Chicago (1923-34), and 8% for U. S. A., 1949. They speak of Austin as having "a significantly higher rate."

4. More recently Malzberg(4) has reported that there has been a remarkable downward trend in the U. S. A. of patient admissions to hospital suffering from the manic-depressive psychoses, *e.g.*, in the New York State Hospital the figures are:

1930	12.8%
1940	6.1%
1950	2.3%

These figures are considerably lower than ours. If we can assume that a strict comparison is possible, we would have to add to our figures the total admissions of manics and hypomanics which would further increase our percentage. Certain of these writers do not make it clear whether they are considering the whole affective group or simply manic-depressive psychoses, but if it is the former, their figures contrast even more strikingly with our own.

RURAL/URBAN RATIO

The area surveyed is a rural one; for our purposes we have considered as urban any town with a population of over 5,000, these being Oban, Campbeltown, Dunoon and Rothesay. The total population in the counties of Argyll and Bute is 75,000 people, of which 44,000 live in rural areas and 31,000 in the towns. Admission proportions are, as set out below, per 1,000 of the population.

	1949-53		1954-58	
Urban	27	0.87/1000	41	1.3/1000
Rural	28	0.63/1000	23	0.5/1000

We found that the urban rate is consistently higher than the rural and if results obtained from our "towns" can in any way be compared with, for example, Austin, Texas (pop. 129,000), our findings would seem to parallel the differential indicated in some American publications. Further analysis of our figures showed that the increase in the urban rate for the second 5-year period was accounted for almost entire-

ly by an increase in the reactive group, the proportion for our first 2 sub-classes (above) remaining much the same. We thought this increase might correlate with known increase in unemployment in the towns at the time, increase in domestic responsibility caused by the end of rationing, and perhaps by a decrease in the numbers of summer visitors. At least 2 of the towns surveyed depend very largely on the "summer holiday" trade, a factor which would not so much affect the rural population.

RELIGIOUS INCIDENCE

From several sources we tried to find the sect distribution in our area. In this we had little success. We had assumed rather arbitrarily that there would be a high correlation between depressive breakdown (one of the writers thought involuntional melancholia) and the Free Church—to our idea, a following of more rigid and inhibitive theology than others in the area considered. Out of our total 119 admissions, 5 were of the Free Church and only 2 of the Free Presbyterian Church; 83 were Church of Scotland, and rather surprisingly to us there were 18 Roman Catholics, the highest incidence of Roman Catholics being in the reactive depression group.

We repeat, we do not have access to accurate figures, but it seems to us that the Free Church following, in the general population of the area considered, is certainly more than our incidence rate of 6%. This is much less than we had expected. Contrastingly, we found that the Roman Catholic proportion in our total group accounted for 16% of the admissions. We would emphasise that there is no indigenous pre-Reformation R.C. group in the counties of Argyll and Bute as there is for example on the island of Barra.

To quote Bellnapp and Jaco again, these writers in their survey of Austin reported that there was a heightened breakdown among Baptist, Methodist and Lutheran sects, and lower rates in the Roman Catholic and Episcopalian following. To our mind, we would not have been surprised at a higher incidence of schizophrenia among Roman Catholics, but we were surprised at finding this indication in an affective group,

particularly in the reactive or exogenous sub-group.

MARITAL STATE

We next considered the marital factor. For comparison, we obtained the figures for the general population in Argyll and Bute from New Register House. The Registrar's population figures for females over 16 (*i.e.*, of marriageable age in Scotland) and our own are compared below.

GENERAL POPULATION (1951 CENSUS)		GROUP SURVEYED
Married :	50.3%	49.6%
Single :	34.9%	40.3%
Widows :	14.0%	8.4%
Divorced/Separated :	.8%	1.7%

The direct comparison between these sets of figures is not statistically valid since our group is selected. But it is valid to make a cross-comparison between the sub-groups—here our percentage in the married group is very close (.7%) to the proportion in the population. Our "single" group, however, is 5.4% higher than our figure for widows, and 5.6% lower than those for the general population. We could only conjecture as to the psycho-pathology reflected in these results. We were not surprised that the depressive rate should be higher for single women, but we would have expected that the rate for widows would also be higher ! These figures in general, however, agree with Rose and Stubs' study (6).

AGE INCIDENCE

Our largest group comprised the 56-65 range. This average is that at first admission. Slater has considered this factor, and it has also been discussed by Schulz.

We found that in both 5-year groups the average age on patient admission was approximately 53 for involuntional melancholia, from 46 to 52 for the manic-depressive psychoses, and from 43 to 46 for the reactive depressions. According to the Registrar General's report for England and Wales 1952-53 the admission rates for affective reactions reached their peak in the 55-64 age group, but for women aged 45 to 54 the rates were not far short of the maximum rate confirmed in our sample. There were in all 41 admissions in the 56-65

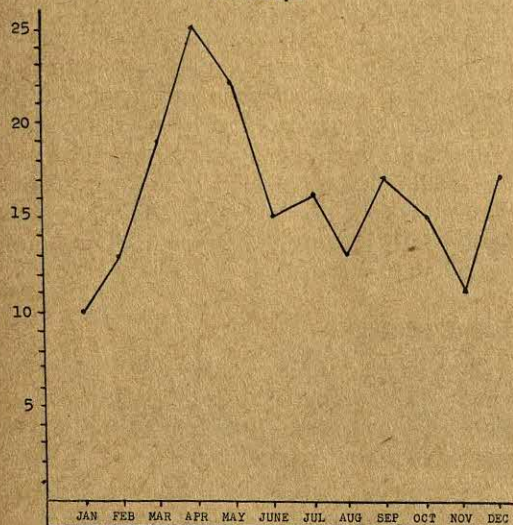

group, and 40 admissions in the 46 to 55 group.

Our study does not include the manias and is thus not strictly comparable, but neither does it include depression occurring in ages over 65. Stenstedt's figures for a geographical area of Sweden contrast sharply with our own. In his graph he gives the highest incidence in women as occurring at 38 years. Again our results are quite different and our clinical impression is that inclusion of the manias and hypomanias would not much reduce this figure.

SEASONAL INCIDENCE

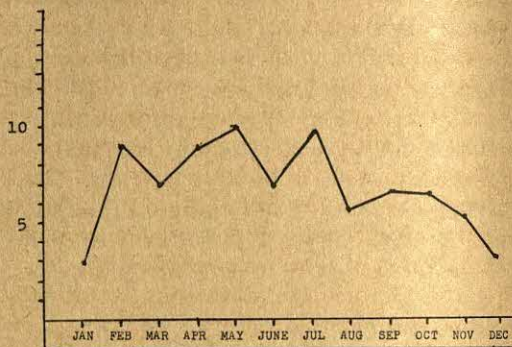

Finally we analysed the seasonal incidence of onset in the group, taking the time of onset as that of admission to hospital. Our readings would argue that the onset of symptoms is earlier than those shown in the graphs (below).

GRAPH 1
Seasonal Incidence
All Groups

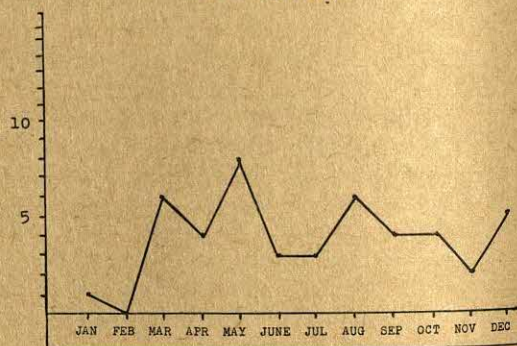

In the admission graphs the figures are for admissions and not individuals. The number of admissions reviewed is 193 (119 individuals). The composite graph indicates an upward swing for the whole depressive group, but the graphs for the individual groups, involutional melancholia, manic-depressive psychoses (depression) and reactive depression respectively, show that this swing is accounted for largely by in-

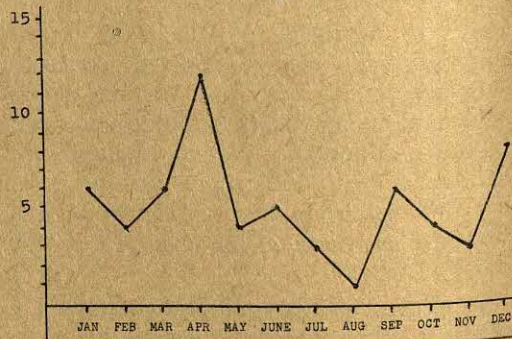

GRAPH 2

creases in the third group, to a lesser extent by the first and little by the second.

DISCUSSION

In this paper we have tried to throw some light on the hypothesis that there is a higher incidence of female depressive breakdown

in the ethnic group which comprises the population of the West Highlands. In this project we were unable to achieve scientific accuracy because (i) by reason of numbers we were able to study only the sub-groups delineated above; (ii) we were handicapped by the variation in nomenclature and definition in current use and were forced to use very rigid criteria in our selection; (iii) our standards for the urban/rural ratio is open to criticism in view of the small size of our urban communities.

In spite of these difficulties, we drew certain conclusions :

1. There is a relatively and contrastingly high incidence of depressive illness in the geographical group studied.

2. The urban rate is consistently higher than the rural rate, and environmental factors are important in this difference.

3. There is no correlation between the incidence of depressive illness and allegiance to an inhibitive religious sect.

4. In the depressive group there is a significant increase in single women and a lower incidence in widows. In the married group there was neither increase nor decrease.

5. Average age for first attacks : involu-

tional melancholia tends to occur at 53, manic-depressive psychoses about 49, and reactive depression about 45.

6. There is a marked rise in the admission rate of the reactive depressions in the spring, but little significant seasonal rise in the other 2 groups.

PATHOGENIC RELATIONSHIPS IN SCHIZOPHRENIA¹

JASON ARONSON, M.D.,² AND STEVEN POLGAR, Ph.D.

This is a study of prehospitalization behavior in the United States Army of soldiers hospitalized at Walter Reed Army Hospital with the diagnosis of schizophrenia.³ Interviews with the officers and enlisted men who had known and worked with the patients indicate that for these patients the development of overtly psychotic symptoms is the outcome of pathogenic relationships with significant other persons in their immediate environment.

The writers, a psychiatrist and an anthropologist, one an officer and the other an enlisted man at the time of the study, interviewed the superiors and associates of 13 patients. Officers were seen in individual sessions, enlisted men and civilians in groups usually averaging 5 persons. Thirty officers, 150 enlisted men and 5 civilians were interviewed in the course of 30 group and 41 individual sessions. These interviews were recorded on tape and later transcribed. Informants were selected with the purpose of including the patient's closest associates. Since the data were collected after the patients' hospitalization, they are, of course, influenced by this fact. In the group interviews information from one informant often stimulated recall on the part of another. Thus, each specific incident previous to hospitalization was usually described by several informants. Even resistant informants, who initially refused to participate, became

involved in the group interaction and ended up by actively contributing to the discussions.

The 13 patients, all enlisted personnel, came from practically every branch of the Army: 3 from the Signal Corps, 2 from the Paratroops, and 1 each from the Army Medical Corps, the Corps of Engineers, the Military Police, the Army Security Agency, the Quartermaster Corps, Armor, Artillery and the Finance Corps. They had been located in 8 different posts in the eastern United States and 2 in France. They ranged from 21 to 30 years of age; length of service in the Army was from 14 months to 12 years. Two were sergeants; 3 specialists; 2 corporals; 3 privates first class and 3 privates. The patients' past histories, obtained by a psychiatric social worker from a visit to their homes and from the patients themselves on the ward, indicated that 7 had had definite episodes of overt psychosis and 4 had had episodes which may have been overt psychosis. In only 2 cases was no history of previous overt psychosis obtained.

It seems reasonable to conclude that on entering the army these patients were individuals with chronic emotional problems who had previously decompensated to psychotic behavior and might do so again. What had been the level of their work performance? And why had the overt psychosis occurred when it did?

We isolated from the interrelationship of the patient and his environment certain dyadic bonds. The bond refers to the relationship between the patient and a significant other person (S.O.).⁴ Our data allow us to infer the presence of such relationships in various ways. The patient himself in our interview prior to the field trip may insist that we see a particular person; patients

³ The milieu therapy ward on which these patients were treated is described in: *The Symptom as Communication in Schizophrenia*, edited by Kenneth L. Artiss. (New York: Grune & Stratton, 1959.)

⁴ The term "significant other" is derived from George Herbert Mead, who has used the concepts "generalized other" and "particular other"; and from Harry Stack Sullivan who has spoken of the "significant person" in the patient's life other than the mother.

may have paranoid delusions centered on an individual; third parties may give us details of transactions between the two; and the individual himself may both directly and indirectly, through being very cooperative or highly resistant, suggest the extent of his participation with the patient. In most cases information from more than one of these sources was available. Purely situational factors which make it likely that a person in the patient's environment will be an S.O. include closeness in the social organization, similarity of background, nearness in living quarters and shared leisure time interests. Family members of the patient will naturally be S.O.'s in the course of events unless the patient has only infrequent contact with them. Situational closeness is not the only determinant of an S.O. relationship. Some of the unconscious factors on the part of the S.O. will be discussed below.

We found it useful to distinguish three types of patient-significant other relationships: 1. Quasitherapeutic; 2. Pseudotherapeutic; and 3. Contratherapeutic.

The Quasitherapeutic Relationship. When we interviewed the men who had what we have called "quasitherapeutic" relationships with the patient we found them to be frank and open. They made no claims to be "leaders of men" or that they possessed the formula for "handling people" as was often the case with those who had pseudo- or contratherapeutic relationships. The personality traits often attributed to "leadership" such as intelligence, dependability, kindness, poise, and decisiveness do not differentiate the quasitherapeutic S.O. from other types. In the recital of events given by the quasitherapeutic S.O. and by other men in the unit, we noted that the quasitherapeutic S.O. conveyed to the patient a feeling of acceptance as a person and an expectation of behavior in accordance with group norms. In other words, he both provided support and set limits. Quasitherapeutic S.O.'s seem to act in terms of the patient's potentialities, not merely in the terms of his immediate performance. Since this interaction is often subtle, it is more difficult to illustrate clearly than the pseudo- or contra-therapeutic relationships.

Pfc. Frost⁵ had been regarded as the worst man in Company A. His work was inadequate, his bed poorly made, his shoes unshined, and he was often reprimanded for his slouching gait. But when he was transferred to Company B a marked change occurred. His work improved, his appearance became more soldierly and he was even seen to smile. We asked the men who had known Pfc. Frost what had made this difference. They felt it had occurred because of his new platoon sergeant, who got along well with Frost. The only description of this relationship the informants were able to give was that this sergeant "just got a knack of handling men." We pressed for an example of this ability. "Well," one man answered, "If someone asks me to do something, say to close the door, I do it. I don't mind doing it, but I don't enjoy doing it. But if that sergeant asked me to do it, I'd enjoy doing it." "What would he say?" "Oh, he'd probably say, 'Hey Shithead, close the door over there!'" In the army mild profanity is often used as a term of approval. "Close the door" is, of course, a request for something to be done. Here, the sergeant has both given support and expected performance.

Another patient had asked his immediate supervisor, a lieutenant, for the day off because he was not feeling well. The lieutenant discussed this with him, recognizing that he was not feeling well but pointing out the work that had to be done. The lieutenant gave him the morning off but required him to come back in the afternoon, which the patient did. By expecting performance, the lieutenant, perhaps, helped to produce it.

Mrs. C., Pvt. Smith's civilian supervisor, recognized that he had problems. Although she was sympathetic toward him, she also insisted on his doing an adequate job. "His attitude was negative to begin with. I had to talk to him many a time. He wouldn't even acknowledge his errors . . . I liked (Smith), I took him aside several times . . . but he couldn't say why he was in these moods when he got into them . . ." Throughout the time he had this relationship with Mrs. C. his performance was not outstanding, but he was productive. At regular intervals he rotated for several days to K.P. duty. Mrs. C. had noted that whenever he returned to his job from K.P. duty he seemed to need more attention and support. After six months Mrs. C. decided that his work did not justify the supervision she felt he required and she had him trans-

⁵ Pseudonyms are used for patients, initials for others.

ferred. From this point on his work deteriorated.

When a patient had a quasitherapeutic bond with a significant other, his behavior, appearance and work performance were usually adequate and sometimes even outstanding.

The Pseudotherapeutic Relationship. In meeting the individuals who established "pseudotherapeutic" relationships with the patient, we were impressed with their cordiality, the warmth and apparent understanding they expressed toward the patient, and the positive feelings other subordinates had toward them. Initially, therefore, we were surprised to discover how poorly the patients had done when this type of relationship was present. In the pseudotherapeutic relationship the S.O. seemed to obtain gratification from having the patient dependent upon him. Characteristically he failed to set any limits on the patient's behavior. Since the patient, apparently insatiable for "understanding," made greater and greater demands, the situation eventually became absurd.

Lt. H., who was in charge of the communications section at a small army post in France, was a college graduate. Pfc. Andrews, who eventually developed overtly psychotic behavior, was the only man in his section who had gone to college. Pfc. Andrews made a point of using big words and was rarely seen without a thick book under his arm. This behavior appears to have struck some unconscious cords in Lt. H., and a pseudotherapeutic relationship was established between them. Another man working in the same office said, "Lt. H. took up more time with (Andrews) than he's took up with any three guys that come into this outfit. And not in a way that he was trying to make (Andrews) do anything." But this was not enough; the patient wanted even more support. The same informant reported, "(Andrews) mentioned the fact that he needed motherly attention and affection, and Lt. H. told him that he was trying to give him fatherly attention and affection . . . And (Andrews) seemed to think that he didn't need fatherly attention. He needed motherly affection." As the lieutenant gave more and more support, Andrews' level of performance progressively dropped.

The S.O. in a pseudotherapeutic bond is

reluctant to acknowledge any difficulties with the patient, and may even ignore overtly psychotic symptoms.

Pvt. Smith had been transferred from a pseudotherapeutic sergeant to a new situation in which he had a contratherapeutic relationship. Within a short time he had developed a delusion that he had been discharged from the army. He went to the office of his pseudotherapeutic S.O. dressed in civilian clothes to say goodbye. The battalion commander interrogated him and then told the pseudotherapeutic sergeant to take Pvt. Smith to the hospital. The sergeant describes this, "The battalion commander wanted him taken over to the hospital . . . I got in my car and started over that way and he said, 'Sergeant,' he said, 'I don't want to go to the hospital.' I said, 'Well, I don't think you *should*,' and so I pulled the car up in the parking lot and we sit there and talked and I told him, 'Now,' I said, 'if there is anything wrong with you, you should go . . . if you think there's anything wrong. Personally I don't think it is, I think it's all figmentation or something in the mind.' So we come back to the company. He went back to work . . ." Later in the day the battalion commander noted that Pvt. Smith was still around and was still delusional; so he ordered two of his officers to take the patient to the hospital.

To recognize that the patient has a psychiatric illness appears to be so threatening to the pseudotherapeutic S.O. that he is unable to do so.

When a pseudotherapeutic relationship exists, the patient sometimes uses failure as a device to get even more support and attention. In several of the cases we have found a pattern of behavior that we have called the "ingenious failure." This is a situation in which the patient has expended much more energy and ingenuity in achieving failure than would have been necessary for him to use in succeeding.

Pfc. Andrews had been trained as a photographer and was given that job. His first trip out he photographed the wrong thing; on the second he left the film out of the camera; the third time he corrected his previous errors but he sent the exposed film to be developed in a white envelope and it was ruined. Since he had been a commercial artist, he was assigned to make a sign. Although he spent three weeks on it and invented his own style of lettering,

it was not good enough to be used. He was then placed on the switchboard, but he insisted on speaking English to the French and on speaking French to the Americans. Finally he was put on K.P. where he produced total exasperation. He was told to mop under a coffee urn. Several hours later he was found still mopping—somewhere he had found a mop with only three strands! From then on his only assignment was to sit by the phone and answer it.

But even answering the phone can be an "ingenious failure." Spec. Ryan was doing inadequately, so he was given the relatively simple task of answering the phone in the Provost Marshal's office. At first he mispronounced "Provost." Corrected in this he took such care in saying it that he failed to hear what the man on the other end of the line was saying. When this was corrected, he began simply to forget what the message was. It was suggested that he write down the conversation. "He answered the phone again and I noticed he was writing on a pad and after the conversation I asked him what went on and again he didn't know—so I checked his notebook and there was just words wrote on top of each other all in a very small area to where . . . he couldn't even read them himself."

Both of these cases of ingenious failure occurred when a pseudotherapeutic bond existed with a superior and the patient could be sure that failure would be met with "sympathetic understanding." In the pseudotherapeutic relationship the patient's work performance slowly but progressively deteriorated.

The Contratherapeutic Relationship. A "contratherapeutic" relationship was characterized by rigid expectations of behavior without any approval on the part of the significant other. In other words, consistent limit setting with no support.

Initially we expected that most of the rough, tough-voiced, "old-army" sergeants would fall into this category. However, many give a great deal of support under the cover of a rough exterior.

Sgt. J. was characterized by the officers of Pvt. Evert's company as the prototype of the old line sergeant. He also used this blunt approach, however, for checking on the patient's finances and calling to task those who had borrowed money from the patient and did not pay it back. He had a quasitherapeutic relationship with Pvt. Evert.

The Adjutant of the Battle Group established a contratherapeutic relationship with Sgt. Downs, a paratrooper, after he was transferred to a Motor Battery. Sgt. Downs had given some shrewd advice to an enlisted man who was facing a court martial and the Adjutant angrily regarded him as a "Stockade lawyer." The Adjutant objected to Sgt. Downs spending time away from training as troop information sergeant, required that he obtain permission every time he left the company area, and ordered the immediate enforcement of a regulation about permission for working outside of the post when he found out that Sgt. Downs held such a job. Sgt. Downs made several requests for transfer, resigned from "jump status" (which in the paratroops usually results in immediate transfer but in this case blocked by the Adjutant), attempted suicide and finally referred himself for psychiatric care. Like other contratherapeutic S.O.'s the Adjutant felt that the patient had fooled the doctors into thinking he was ill in order to get out of the immediate situation.

Another patient was hospitalized shortly after working in the same office with Sgt. L. who told us: "Yes, sir . . . in my experience . . . with personnel of his character, I wouldn't take him across the street . . . And I think, my own way of looking at it, if he had more strict discipline instead of so much babying which he got, throughout the time I seen him, he was nothing but mollycoddled and handled with kid gloves. If he got a good kick where it would have done the most good, he probably would have come out of it. Now, I may be speaking like an old soldier . . ." Sgt. L. asked the patient to make some signs for his letter-boxes: three of them "In," three "Hold," and three "Out." "Hah! I got all nine of them 'Out.' Now, I ask him why? And he said, 'Well, I don't know.' Well, in my rough manner, I told him to get his head back there and go to work and do it right. And when he seen that he wasn't going to fool me, or at least that is my idea I got, then he came back with the job done." He did get out from the relationship a week after this incident by becoming overtly delusional.

When patients had a contratherapeutic relationship with their supervisors they usually made frantic efforts to be transferred. If these failed, they often went AWOL. If neither of these techniques resulted in removal from the relationship, the patient developed overtly psychotic symptoms.

The Significant Other and the Total Environment. Until now we have treated the relationship between the patient and his S.O. as if they were independent entities. We must also consider the interplay between the patient, S.O., and less important individuals in the environment.

When a quasitherapeutic relationship held, this was often the result of two or more S.O.'s acting together. Master Sergeant D., the Major K. took turns in setting limits on Cpl. Green's habit of coming in late, and they both gave him intermittent support. Two Master Sergeants in another case, one as the chief of his section and the other as First Sergeant, similarly complemented each other.

Objects were routinely used by the patient in attempts to gain attention, or to set up barriers, or both. Three of the patients shared an interest in photography with their peers. Two liked to turn their radios up loud and insisted on playing music others were less enthusiastic about; four other patients were often seen in the company of thick, abstruse books.

When an officer had a pseudotherapeutic bond with a patient, the sergeants between them modified their behavior toward an approximation of such a relationship. The company clerk in the Smith case, for example, modeled his actions after the First Sergeant. Pfc. Andrew's sergeants did not set limits on his behavior once they saw the relationship between him and Lt. H.

Transfer of the patient to a new group results in the loss of relationships he had previously established. Unless a new quasitherapeutic relationship is established with a single S.O. or with a combination of several S.O.'s his work performance declines. If the new relationship is pseudotherapeutic this decline is gradual; if it is contratherapeutic the decline is abrupt with the patient making various efforts to escape from the situation before using psychotic techniques.

The factors that determine whether a relationship with a particular S.O. is quasitherapeutic, pseudotherapeutic or contratherapeutic appear to be largely unconscious. The pseudotherapeutic S.O. may be unconsciously responding to his own dependency needs by seeking the vicarious

gratification of having someone dependent on him. The contratherapeutic S.O. may angrily reject the patient's demands for support because of denial and repression of these same factors in himself. Due to the limitations of this study there is insufficient information on the significant others to document these dynamics.

All of us have relationships with significant others. In the normal course of day to day events these significant others may perform surrogate ego functions for us. We have all experienced the stimulation of interaction with others, when astute questions have helped us think more clearly, when reassurance has helped us achieve difficult goals, or when insistent demands have helped us complete a job we would otherwise have left undone. A measure of leadership is the extent to which the leader succeeds in helping the individual to perceive, understand and handle the inner psychological needs and the outer reality situations with which he must cope. We all have had experience with quasitherapeutic, pseudotherapeutic, and contratherapeutic relationships and yet not all of us have developed psychotic symptoms. Why did these patients become overtly psychotic? These patients—whatever the predisposing factors may be—are individuals with chronic ego defects. Past history reveals that most of them have shown psychotic behavior some time in the past. In situations where a significant other provides surrogate ego functions they get along fairly well, and in some cases very well indeed. But when these ego functions are not performed, lacking adequate inner resources, they resort to overtly psychotic behavior.

SUMMARY

The authors interviewed 185 individuals at 11 army posts to gather data on performance level of 13 soldiers who developed overtly schizophrenic psychoses after at least one year of service in the army. The level of work performance and the development of overt psychotic symptoms depended on the type of relationship established with significant other persons. Three types of relationships were distinguished: quasitherapeutic, pseudotherapeutic, and contratherapeutic.

The *quasitherapeutic* relationship is one in which the significant other conveyed to the patient a feeling of acceptance as a person and an expectation of behavior in accordance with group norms, *i.e.*, he both provided support and set limits. In the *pseudotherapeutic* relationship the significant other, who seemed to obtain some gratification from having the patient dependent upon him, provided solely support. Rigid expectations of work performance without any emotional support was characteristic of the significant other in the *contratherapeutic* relationship.

Information from those who knew him indicated that the patient did adequate, sometimes even outstanding work in the quasitherapeutic relationship. This relationship was disrupted when either the patient or the significant other was transferred to another post. In the pseudotherapeutic relationship the patient continually made great-

er demands for support and his work performance progressively deteriorated. In the contratherapeutic relationship the patient rapidly developed overtly psychotic symptoms. Both the pseudotherapeutic and contratherapeutic relationships led to hospitalization.

It has been pointed out by a number of authors (Nathan Ackerman, Gregory Bateson, Don Jackson, Adelaide Johnson, Erich Lindemann, and Stanley Szurek) that deviant behavior of an individual may represent psychopathology of the family group. The data gathered in this study indicate that groups other than the family can be pathogenic. Psychiatric attention to the family of a patient has both contributed to understanding of the development of psychopathology and led to new therapeutic methods. Extending this interest to the patient's relationships in his work and social groups may produce similar results.

ATTEMPTED SUICIDE IN ADOLESCENTS¹

JACOB TUCKMAN, Ph.D., AND HELEN E. CONNON, M.S.²

Suicide is an important public health problem. In the United States, suicide is the sixth leading cause of death among those 15 to 24 years old, fifth among those 25 to 34 years old and 35 to 44 years old, and seventh for those in the 45 to 54 age group(4). Suicide ranks eleventh for the total population and eighth for the total white male population. While these statistics show that suicide affects individuals at all age levels, particularly those in their most productive years, relatively little attention has been given to this problem. This may be accounted for by the difficulties in approaching the problem objectively and by the complexity of the factors leading to suicide. Some of the variables are known, such as the relationship of suicide to age, sex, race, and marital status, but there are other more elusive factors with respect to the range and interplay of personal characteristics and the social environment.

The dynamics in suicide might be better understood if the individual's background were known, with emphasis upon his early development, the manner in which he was reared, the emotional climate in the home, the traumatic events to which he was exposed, his customary way of reacting to stress, *etc.* Reconstruction of an individual's life experiences is not an easy undertaking and is even more difficult for a suicide. Persons knowing most about him may be unreliable sources of information owing to defensiveness stemming from strong guilt feelings about his death. Presumably the amount of unreliability will vary with the closeness and relationship to the deceased. A more fruitful approach, therefore, would be to focus upon attempted suicide rather than suicide and upon children and adolescents rather than adults because (a) those

who attempted suicide can be interviewed, (b) responsible relatives, anxious about future attempts, may be less defensive in discussing the situation, and (c) reconstruction of the life situation is easier for children and adolescents than for adults and especially older adults.

This study is concerned with 100 consecutive attempted suicides by children and adolescents under the age of 18 coming to the attention of the Philadelphia Police Department during 1958 and 1959. Eighteen was used as the cut-off point because persons under this age fall under the jurisdiction of the Juvenile Aid Division of the Police Department. This division is often contacted by parents seeking emergency assistance or by hospitals where the adolescent is taken for treatment. Although suicide or attempted suicide is not a misdemeanor in Philadelphia, the Police Department not only provides help in emergency situations but also investigates the circumstances surrounding the attempt, to rule out any possibility of attempted homicide. Information about the characteristics of the adolescents at the time of the attempt was obtained from the official police reports.

During the 2-year period under study, there were 20 additional attempted suicides that came to the attention of the Poison Control Center of the Philadelphia Department of Public Health. These cases were not included in the study because little or no information was available. During the same period there was only one individual under the age of 18 classified as a suicide by the Office of the Medical Examiner.³ Based on reports from just two sources, *i.e.*, the Police Department and the Poison Control Center, the ratio of attempted to successful suicides was 120 to 1 among persons under age 18. This is probably an under-

¹ The authors are indebted to Mrs. Martha Lavell, now with the Commission on Human Relations, Philadelphia, for her helpful assistance in this study.

² Respectively, Division of Mental Health, and Division of Statistics and Research, Community Health Services, Philadelphia Dept. of Public Health.

³ The Medical Examiner of the Philadelphia Department of Public Health exercises by statute exclusive jurisdiction for determining the cause of death in all cases not attended by a physician or not due to natural causes.

estimation. Discussions with clinic directors in general hospitals as well as data from this study suggest that an unspecified number of attempted suicides do not come to the attention of any official agency. The ratio of attempted to successful suicide among adolescents in this study and that of 50 to 1 in another (3), is considerably higher than that found among adults where ratios have been estimated to be as low as 2 to 1 (2), although 5 to 1 has been reported more often.

The distribution of the attempts, by sex, race, and age is shown in Table 1. The age distribution shows that the overwhelming majority of attempts (87%) were made between the ages of 14 and 17. The ratio of 6 females to 1 male is considerably higher than the 3 to 1 sex ratio usually reported for attempted suicides among adults. The race distribution shows 52% white and 48% nonwhite. Since nonwhites constitute 31% of the total population between 10 and 19 years of age in Philadelphia, it is evident that they are overrepresented in the attempts, contributing one and one-half times their expected rate. The overrepresentation of nonwhites in the sample should be interpreted with considerable caution since whites, having greater resources, may prefer to use private facilities rather than official agencies in emergencies such as attempted suicide.

TABLE 1
Attempted Suicides by Age, Race and Sex

Age	White		Nonwhite	
	Male	Female	Male	Female
10	0	0	0	1
11	1	1	1	1
12	0	1	0	1
13	0	1	1	4
14	0	10	1	6
15	2	8	3	9
16	2	17	0	8
17	3	6	0	12
Total	8	44	6	42

There were no race differences with respect to any of the factors covered in this study. Age comparisons showed a significant difference only with respect to the reported circumstances precipitating or leading to the attempt. No sex comparisons were made

since there were only 14 males in the sample. Therefore, data will be presented for the total group only.

As might be expected among adolescents, the majority, 69%, were students. Seven percent were employed, 16% were in the labor market but out of work, 6% were engaged in family responsibilities including the care of children, and no information was available in 2% of the cases. No relationship was found between attempt and time of year when analyzed by month or by season, but there was a significant association with time of day. About 2 of every 3 attempts (63%) took place between 3:00 P.M. and midnight; fewer attempts (33%) occurred between midnight and 3:00 P.M., periods usually devoted to school or sleep. In 4% of the cases, the time of the attempt was not stated. Most of the adolescents (87%) attempted suicide in their own homes.

Eighty-three percent of the cases ingested poisonous substances, 5% inhaled illuminating gas, and 12% used a variety of other methods such as slashing wrists, jumping from high places, *etc.* Of those who ingested poisons, 25% used analgesics such as aspirin or aspirin compounds; 42% used sleeping pills or tranquilizers; 17% ingested medical preparations usually prescribed for external use such as iodine, rubbing alcohol, oil of wintergreen; and the remaining 16% used nonmedicinal preparations such as rat poison, ammonia, and bleach.

The circumstances precipitating or leading to the attempt, reported by the adolescent and those reported by the parent or responsible adult are shown in Table 2. The circumstances most frequently reported by the adolescents and by the parents involved conflict around events which are not uncommon in homes with adolescent children. These include responsibility for household chores, keeping of hours, personal appearance, school attendance, homework, choice of friends, visiting relatives, *etc.* About 1 of 5 adolescents reported difficulties with the opposite sex, situations ranging from a broken date to rejection following pregnancy; but only 1 of 10 parents referred to such difficulties as the basis for the attempt. As might be expected, difficulties with the opposite sex were reported more frequently by those 16 and 17

years old (25%) than by those under 16 (12%). Twice as many adolescents as parents (14% compared with 7%), mentioned fear of being unloved, fear of punishment, fear of failure, or fear of not measuring up to parental expectations. Sixteen percent of the cases and 11% of the parents reported other circumstances, some more explicit than others, *e.g.*, prolonged physical illness, psychotic episodes, and parent-child conflict around serious delinquent behavior. In 14% of the adolescents but in 33% of the parents, the precipitating circumstances were not stated in the police report or were reported by the respondent as not known. The difference between the circumstances reported by the adolescents and those reported by the parents is statistically significant (at the .01 level).

TABLE 2
Circumstances Precipitating the Suicidal Attempt
(in Percents), Reported by Adolescents and by
Parents

Circumstances	Adolescents	Parents
Conflict around common events	38	41
Difficulties with opposite sex	18	8
Specific fears	14	7
Other	16	11
Not stated or not known	14	33

$$\chi^2 = 14.90 \text{ df} = 4 \text{ P} = < .01.$$

Examination of the not-stated and not-known responses suggests that the parents of responsible adults were unaware of important problems in the lives of their children because of the reluctance of the adolescent to discuss these problems, the lack of parental interest or a poor relationship between parent and child. Of the 33 adults who gave or knew no reason for the attempt, there were 28 adolescents reporting the precipitating circumstances. In one-half of these cases, the adolescent reported difficulties in interpersonal, primarily "boy-girl" relationships; in one-seventh of the cases the adolescent reported feelings of being unloved; and in the remainder miscellaneous reasons were given. Of the 14 adolescents not reporting reasons for the suicidal attempt, there were 9 adults who gave information on the precipitating circumstances. In almost one-half of these

cases, the adult reported conflict around presumably common occurrences; for the others various reasons were given.

Information concerning the background of the cases was obtained by contacting health and welfare agencies to which the adolescent or his family had been known prior to the attempted suicide. These organizations were identified through the Social Service Exchange, the clearing house for registration of cases known to community agencies. A letter describing the purpose of the study was sent to each agency, requesting information regarding the nature of its contact with the adolescent or his family, with particular emphasis on relevant background factors. Public agencies made their records available for study; private voluntary agencies provided written summaries. Data obtained from health and welfare agencies were incomplete for many areas of interest and in general yielded little information not already available from a knowledge of the functions of these agencies. This is not surprising since these organizations gathered information to carry out their specialized functions and not to answer specific questions regarding persons who have shown suicidal behavior.

The health and welfare agencies to which the adolescent or members of his family had been known prior to the attempted suicide were classified as follows:

1. Health: in- or outpatient care at hospital or clinic for a physical condition.
2. Psychiatric: in- or outpatient care.
3. Economic: public assistance.
4. Protective: care and placement of neglected children.
5. Delinquency: police, court, correctional institution, probation.
6. Domestic relations: Municipal Court for Domestic Relations.
7. Counseling: family, school, marriage clinic.
8. Other: Red Cross, legal aid, day care center, *etc.*

The number of health and welfare agencies to which the cases under study or members of their families had been known ranged from 0 to 19 per family. Twenty-five percent of the families had no contacts, 48% had from 1 to 5 contacts, 21% from 6 to 10, 4% from 10 to 15 and 2% had 16 to 19 con-

tacts. The total number of agency contacts was 365, distributed as follows: delinquency, 118; protective, 55; domestic relations, 39; health, 39; counseling, 39; economic, 29; psychiatric, 26; and other agencies, 20. Included in the 75 families known to health and welfare agencies were 53 of the cases under study, 23 mothers, 13 fathers, and 32 siblings. Although no specific data are available regarding the extent to which the general population utilizes the services of health and welfare agencies in the community, it seems reasonable to say that the families in this study have had greater contact with welfare agencies than most families. A comparison of attempted suicide cases known to social agencies with those not known to any agency showed no significant differences between the two groups with respect to any of the factors covered in this study.

The total number of agency contacts may be misleading since recurring or chronic problems within families may have contributed a disproportionate number of contacts. Therefore, only unduplicated contacts, by type of agency and by family composition, were considered and are shown in Table 3. For example, if 1 of the cases had been known to 6 different delinquency agencies, the number of contacts with this type of agency was reported as only 1 contact in Table 3. If within the same family the mother had also been known to 3 different delinquency agencies, the father to 2, and 3 siblings to 6, the number of contacts in Table 3 was shown as only 1 contact for the case under study and none for the other members of his family. However, if these contacts by mother, father, and siblings occurred in a family where the case under study was not known to any delinquency agency, Table 3 would show 1 contact for other family members and none for the case under study. For domestic relations, public assistance, and protective agencies, contacts are reported in a separate category for the family as a whole.

The data in Table 3 show that family disorganization and the factors usually associated with family breakdown characterize the life experiences of the cases attempting suicide. Parental neglect, cruelty, and even abandonment were not uncommon. In 29%

of the cases the home situation was so poor that intervention by the Society for the Prevention of Cruelty to Children was necessary; in more than one-half of these cases some or all of the children were taken from the parents and placed in institutions or foster homes. At the time of the attempted suicide, almost one-half (47%) of the cases were from homes broken by separation, divorce or death by one or both parents. The extent of broken homes may be an underestimation since in 29% of the cases no information was available regarding the marital status of the parents.

TABLE 3
Percentage of Unduplicated Agency Contacts by
Type of Agency and by Family Composition

Type of Agency	Adolescent	Other Family Members	Family as a Unit	Total Contacts

Counseling	10	6	16	32
Protective	0	0	29	29
Economic	0	0	28	28
Health	9	15	1	25
Psychiatric	14	3	0	17
Other	3	9	2	14

More than 1 of every 4 families had been or were recipients of public assistance in the period following World War II when the level of employment was high. The need for public assistance is especially significant since parents of adolescent children are generally in their most economically productive period. Four of 10 families were known to the Municipal Court of Domestic Relations. Some of these contacts involved court action against the father for failure to support his family or his illegitimate children; others required intervention because of severe conflict between the parents. About 1 in 3 families had had contact with counseling agencies: one-half of these cases were parents seeking help with marital problems; the others involved the adolescents attempting suicide or their siblings who presented problems in school with respect to attendance, performance or behavior. About 1 of 6 families had been known to a psychiatric clinic or hospital. However, the records of the counseling

agencies and psychiatric facilities suggest that these contacts were initiated by the school or general hospital clinic and not by the family which had little understanding of when or where to seek help. In 51% of the families, there was a history of delinquency, often extending over a period of years; of these more than 60% included the adolescents who attempted suicide. The amount of delinquency may be an underestimation since all who engage in delinquent behavior do not necessarily come to the attention of the police or courts. Some of the delinquency contacts were nonarrests, *i.e.*, cases never brought into court; others covered the entire range of offenses resulting in arrest, probation or sentence to a correctional institution. Essentially, there was little difference between nonarrest and arrest cases with respect to the seriousness of the offense. The action taken against the offender depended upon his age, the attitude of the police officer, and the likelihood of rehabilitation through the services of a community agency.

Little information is available on action taken by the family to prevent a recurrence of suicidal behavior. The records stated that some police officers advised the family to seek psychiatric or other specialized assistance. These suggestions or other considerations motivated some families to examine their own behavior and attitude toward the adolescent, and to take measures to prevent future attempts. However, very few families sought professional help. Using contacts with psychiatric or counseling agencies during the 6-month period following the suicide attempt as evidence of interest in seeking professional help, only 3% of the families initiated such contact.

CONCLUSIONS

Two important findings emerge from this

study of 100 children and adolescents who attempted suicide. The first is the association between attempted suicide and family disorganization. This has been demonstrated for adults by Batchelor and Napier who reported broken homes (deprivation in childhood of a normal life with parents) in 58% of 200 consecutive cases of attempted suicide admitted to a general hospital(1). Although the cases ranged in age from 15 to 83, only 6 were under 20. The second finding is the association between attempted suicide and delinquency, each representing acting-out behavior, not stemming from mental illness, in an attempt to control the social environment. The interrelatedness of attempted suicide, family disorganization, and delinquency is in line with the finding of investigators who have shown that family disorganization, with the concomitant factor of emotional deprivation in the formative years, gives rise to a host of problems which take different forms, *e.g.*, mental illness, morbidity, delinquency, and crime. Prediction of the specific form that the deviant behavior will take is most difficult since it depends upon the identification and understanding of the factors that contribute to the child's personality and behavior. Such factors include the behavior of the parents, their attitudes and values, the practices employed in the rearing of children, the nature of the parent-child relationship, and many other personal and social characteristics.

CHANGING CONCEPTS OF PSYCHIATRIC EVALUATION

LEONARD T. MAHOLICK, M.D., AND DAVID S. SHAPIRO, PH.D.¹

When the patient arrives at the community mental health center, our aim is to help him as quickly and effectively as is possible with a minimum of confusion and "handling." To accomplish these goals, it was necessary to challenge some of the sacred cows of the "team" approach. Let's see what was done about the reception, diagnostic appraisal, and disposition of new patients at The Bradley Center.

Our present method of evaluating patients consists of the following procedures: The applicant is seen by our clinical secretary who gives him a folder of self-administered tests and questionnaires, which are to be completed and returned before his initial interview. The battery includes the Cornell Index, the Mooney Problem Check List, the M.M.P.I., and an especially prepared biographical questionnaire. The patient is then seen by the psychiatrist-medical director, who, with the help of the previously scored and prepared material, is able to formulate a reliable diagnostic impression, appraise resistances and defenses, prescribe a form of treatment or make other disposition of the case, discuss fees, and assign the patient to a staff member for psychotherapy with relative sureness. Other members of the staff, psychiatric social worker and psychologist, are used as consultants for further evaluation when this is needed. The above method is used routinely in our handling of adults. Child guidance and marital problems have required some modification of this formula (4).

What we have gradually evolved is a pre-interview screening and personality assessment battery. The use of the biographical questionnaire has proven to be particularly valuable, giving us in a majority of instances information and insights into the patient's background and his pattern of handling stress which could not be duplicated in many information-gathering

interviews. It is our impression that the patient benefits considerably from the experience of systematic self-examination required to fill out all forms.

When The Bradley Center opened 6 years ago, we adopted, with several revisions, the traditional method for evaluating applicants which (with numerous exceptions due to specific circumstances) consisted essentially of 4 steps: an initial interview with the psychiatric social worker; an examination by the clinical psychologist; an interview with the psychiatrist; and one or more staff conferences for final diagnosis and disposition.

At the Center patients were seen initially by the psychiatric social worker for at least one interview lasting 1½ hours. Psychological examinations were given infrequently when specifically indicated. Then the case was discussed at a regularly scheduled staff conference where the patient was interviewed by the psychiatrist for 20-30 minutes. The staff then discussed the patient and arrived at a diagnosis and recommendations.

We soon became aware of a number of complaints and problems:

1. The cost of our diagnostic evaluation, which we as a fee-charging clinic passed on to the patient, was excessively high. This was true in spite of the fact that our fees are moderate and do not represent the full cost of the services rendered. Thus the procedure was also proving costly to the Center.

2. The staff was spending up to 30% of our clinical time in diagnostic work thus limiting the amount of time available for treatment.

3. Patients complained of long delays and devious routes taken before final disposition.

4. Referring professional persons, particularly physicians, could not understand why acutely disturbed patients they had referred could not be seen directly by the psychiatrist or receive treatment for many weeks.

To determine how essential our tradi-

¹ Respectively, Med. Dir., and Chief Clinical Psychologist, The Bradley Center, Inc., Columbus, Ga.

tional intake, diagnostic, and staff conference methods were, we conducted a simple study. A questionnaire was prepared for the staff containing 11 items considered important in arriving at a diagnosis and treatment plan. Included were questions about clinical diagnosis, character diagnosis, level of anxiety, capacity for insight, adequacy of reality testing, social competence, capacity for forming close interpersonal relationships, capacity to benefit from psychotherapy, and others. The questionnaire was filled out twice by the staff: the first time before the patient was interviewed but after all reports had been presented and discussed in a staff conference; the second time after the patient had been interviewed at a staff meeting and the results discussed. A sample of 30 consecutive adult patients was used. The results showed that the agreement between pre- and post-interview conferences opinions on clinical diagnosis was 50%; on character diagnosis only 42%. Major changes were found in 33% of opinions about clinical diagnosis and 50% of opinions about character diagnosis. Agreement on non-diagnostic questions dealing with opinions such as level of anxiety, capacity for insight, capacity to benefit from psychotherapy, and others, ranged from 60% to a high of 83%.

These results suggested that conventional methods of intake and preliminary study permit a wide range of uncertainty and disagreement; that they require duplication in order to achieve reliability; and that they do not contribute significant information commensurate with the time and money invested in such procedures.

Thus it was decided to strip our evaluation process to the bare essentials. In a psychiatric clinic, one of the essentials is that the medical director must assume responsibility for diagnosis and disposition. It was decided that, since the patient must ultimately get to the psychiatrist, we would have the psychiatrist see the patient first. The psychiatrist would then be in the position to take immediate actions such as the use of chemotherapy, referral to a hospital if required, and other emergency steps as indicated. If emergency action was not required, the psychiatrist had the authority to assign patients suitable for thera-

py to one of the staff members. If further study was necessary, the psychiatrist would call on other staff members to assist. All conventional and routine staff meetings were abolished as were routine social work interviews and testing. This change produced immediate, observable, and quite dramatic results. There was an immediate increase in the number of treatment hours available; the delay between application for services and the start of treatment dropped markedly; the cost of diagnostic services dropped considerably; there was a noticeable improvement in patient morale and in relationships with professional groups in the community.

The medical director became aware of the burden of conducting long, detailed diagnostic interviews with an unknown patient. He found it necessary to spend 1½ hours in each interview. We gradually adopted as our long range research effort the development of techniques for large scale mental health screening and assessment and the demonstration that such techniques are feasible and economically advantageous in conducting community-wide programs for the improvement of mental health(3). A key feature of this project was the assembling of a battery of screening and assessment devices which were simple and economical to administer and score, did not require a great deal of professional time, and could eventually be simplified for use by nonpsychiatrically trained professional people such as physicians, nurses, social workers, ministers, and others. We assembled the battery mentioned previously and constructed a biographical questionnaire. We administered the battery to a sample of 101 normal subjects and, in addition, conducted 2 one-half hour interviews with each subject. The medical director, realizing its usefulness, started using the battery of tests for the pre-interview evaluation of patients. Very soon it became clear that this method produced a considerable decrease in the amount of his time required for the diagnostic interview. At times, it was possible for patients to have started psychotherapy with another staff member within days after the initial interview. This material along with a brief, pointed résumé of the psychiatrist's clinical

findings made it easier for other staff members to follow through with psychotherapy in a more efficient manner.

The magnitude of the benefits derived from the changes in our methods of evaluating new patients is reflected in our annual figures for diagnostic and psychotherapy interviews over a 2-year period, during which the changes were introduced and during which we were operating with the same staff. In the year ending April 31, 1958, 732 diagnostic interviews and consultations and 2,543 psychotherapy interviews were conducted. For the following year, 368 diagnostic interviews and consultations and 2,864 psychotherapeutic interviews were conducted. Thus, in one year, there was a decrease of 266 diagnostic interviews and consultations and an increase of 321 psychotherapy interviews. These figures tell only part of the story; there was a very sharp rise in research activities, reflected in an increase in research conferences from 8 during the 1958 period to 197 during the 1959 period. Much of the time for a rapidly expanding research program was made available to us by the reduction in unnecessary diagnostic procedures and conferences.

Early results in our first research project, begun in the spring of 1957, indicate we have developed simple, effective and systematic methods for mental health assessment, counseling, and referral which can be readily taught to such professional groups as physicians and ministers. With these techniques incorporated into their everyday practice, they can more effectively meet the needs of persons with psychiatric and social problems(5, 6).

A second research project has dealt with Frankl's claim that the great illness of our time is the sense of a loss of meaning or purpose in life. In an attempt to verify this and determine some of its implications diagnostically and therapeutically, we have devised a Purpose-in-Life Test and are in the process of gathering data from both patient and nonpatient groups which will be published later.

It is our impression that many of the mental health clinics are groping for more effective methods to meet the needs of the very large number of troubled persons com-

ing to them for help(2). A willingness to experiment and a critical examination of the sacred "traditional" procedures would, in a very great number of cases, expose duplication and inefficient use of time and skills. Screening devices could materially reduce waiting lists, and lead to early referral of patients to more appropriate sources of help.

Our findings and experience present a challenge to the philosophical orientation of the traditional psychiatric team. Too often the "team" approach has simply meant having 2 or 3 professional persons doing the work that could be done adequately by one. Too often the "team" functions in such a way as to force the patient to adapt or adjust to the clinic's rigidity instead of the clinic being more flexible to better meet the needs of the patients(1). With our new methods each professional member of the clinic staff faces a challenge to increase his proficiency or face a loss of status. The psychiatrist is faced with the most immediate challenge to become a more astute diagnostician with minimal information. He must become more informed of community resources. Perhaps the most striking challenge to the psychiatrist is the pressure on him to accept the potentialities of other professions to do psychotherapy; to demand their continued improvement in this service; and finally to communicate his confidence in the nonmedical therapist to the patient. The psychologist is under pressure to increase his skill and responsibility in conducting psychotherapy. In the area of diagnostic skill, he may be forced to minimize or discard the routine use of long, expensive and poorly validated tests and learn to make more adequate use of simpler, objective tests. The psychiatric social worker also is challenged to develop psychotherapeutic skills. The long intake interview and report which takes so much of the social worker's time may eventually prove inefficient and uneconomical and the use of shorter, more pointed consultations may be required. The training schools for social workers and psychologists may be challenged to improve training facilities in psychotherapy and counseling.

We believe that our work and the work of many others in this field will eventually

result in an ever growing demand for more effective, economical methods for better serving the psychiatric outpatient in our communities.

AUTOMOBILE ACCIDENTS, SUICIDE AND UNCONSCIOUS MOTIVATION¹

MELVIN L. SELZER, M.D., AND CHARLES E. PAYNE, M.D.²

Suicide or attempted suicide is usually considered in terms of conscious and overt self-destructive action. However, data introduced in this paper³ suggest that many persons with self-destructive inclinations may attempt to destroy or injure themselves through automobile accidents and that these accidents are rarely perceived as suicidal attempts by either the driver or the public.

Failure to reduce the large number of traffic accidents through punitive or educational measures has resulted in diverse efforts to assess the personalities of drivers who incur more accidents than their fellows. Conger, *et al.*, stressed the poor control of hostility, low tolerance for tension, dependency, egocentricity, and unreflectiveness found in their accident group(1). Tillman and Hobbs, investigating both low and high accident taxicab drivers, found that the latter could not tolerate and were chronically in revolt against authority. This group was also characterized by antisocial attitudes, impulsivity, distractibility, and marital and fiscal irresponsibility(2). The above investigators made no reference to suicide or depression as a contributory factor but did find evidence of poor hostility control.

Recently, the authors initiated a research effort to determine if any correlation existed between suicidal disposition and automobile accidents. Interviews were held with 30 alcoholic and 30 non-alcoholic male inpatients who were undergoing psychiatric treatment at the Veterans Readjustment Center of the University of Michigan. Data obtained included suicidal attempts, past or present persistent preoccupation with suicidal thoughts, and a history of all traffic accidents for which the patients were re-

sponsible. (Inasmuch as all patients were undergoing psychotherapy, the data relating to suicidal preoccupation could later be confirmed with the therapist. It was our impression that the psychotherapy contributed to the patients' candor in revealing traffic transgressions and suicidal preoccupation.)

In the 60-patient group, 33 men admitted having seriously considered committing suicide or reported one or more suicidal attempts while 27 men disclaimed a history of either. The 2 groups did not differ significantly in miles driven or socio-economic background. The median age for each group was 33.5 years with a total age range for both groups of 24-58 years. Psychiatric diagnoses of the suicidal and non-suicidal groups respectively were: personality disorders (predominantly passive-aggressive personality), 20 and 18; schizophrenia, 9 and 7; psychoneuroses, 4 and 2; and chronic brain syndrome, 0 and 1.

The 33 "suicidal" men were responsible for 89 automobile accidents with a mean of 2.70 accidents per person. The 27 non-suicidal patients accounted for 36 automobile accidents or 1.30 accidents per person (Table 1). Thus, there were over twice as

many accidents per person among the group who had serious suicidal thoughts or had made suicidal attempts than among those who had not considered suicide. Because of the distribution of accidents (Table 2), a test on logarithmic transformation was used which established a significant accident difference between the 2 groups in the range of .01-.05.

¹ This study was financed by a grant from the Waggoner Research Fund.

THE ALCOHOLIC GROUP

Since the alcoholic's responsibility for automobile accidents might be attributed solely to intoxication(3), the accident breakdown within the alcoholic group was of particular interest. Of the 30 alcoholics interviewed, 17 were suicidal using the above criteria. These 17 suicidal alcoholics were responsible for 63 automobile accidents whereas the 13 non-suicidal alcoholics precipitated a total of 24 accidents, yielding mean values of 3.70 and 1.77 accidents per person for each group respectively (Table 1). Here again the suicidal group accumulated a mean accident value twice that of the non-suicidal group. This difference was also significant ($p=.05$), and of course independent of the patient's alcoholism which was a constant for the entire group. It appears, then, that intoxication *per se* may not be the sole determinative factor in automobile accidents caused by alcoholic drivers (4). This may be of importance in light of several investigations indicating that the so-called "drinking driver" who is brought to the attention of the police or the coroner is quite frequently an alcoholic rather than a social drinker who has overimbibed(5, 6, 7).

In the 30-patient non-alcoholic group, the 16 suicidal patients reported 26 accidents, and the 14 non-suicidal patients reported 12 accidents. The respective mean values for accidents per patient were 1.62 and 0.86 (Table 1). Although the non-alcoholic, suicidal group averaged almost twice as many accidents per patient as the non-alcoholic, non-suicidal group, the dif-

ference here proved to be of borderline significance ($p=.06$).

ATTEMPTED SUICIDE

On the assumption that the individuals who converted their suicidal thoughts into action would have more automobile accidents than those who did not, the 33-patient suicidal group was broken down into the 12 patients who had actually attempted suicide and the 21 who had merely been preoccupied with suicidal thoughts and fantasies. The 12 "suicide attempters" (9 alcoholics and 3 non-alcoholics) accumulated 43 accidents while the remaining 21 patients in the suicidal group reported a total of 46 accidents, yielding mean values of 3.60 and 2.20 accidents per patient respectively. This difference was not statistically significant (perhaps due to the small numbers involved), and hence we could not say that the increased accident rate of persons with suicidal preoccupation depended on whether or not they actually had attempted suicide in the past. It is interesting to note that of the 21 conscious suicidal attempts reported by the 12 patients who attempted suicide only one attempt was made by the patient deliberately wrecking his car.

COMMENT

There are a number of compelling reasons for the self-destructive individual to become the victim of his own erratic driving. Suicide is a regressive phenomenon. It has even been described as a perversion: "an indirect form of gratifying instinctual drives in a manner more primitive and more infantile

than normal"(8). The overt expression of self-destructive impulses—whether fundamentally oral, libidinal, or aggressive—implies that the individual has reached a *modus vivendi* with his superego in order to accomplish his regressive suicidal task. The automobile lends itself admirably to attempts at self-destruction because of the frequency of its use, the generally accepted inherent hazards of driving, and the fact that it offers the individual an opportunity to imperil or end his life without consciously confronting himself with his suicidal intent. All but one of the men in this study perceived their traffic mishaps as completely fortuitous.⁴

Stone has pointed out that cultural and situational factors may influence the mode of suicide selected (11). Certainly ours is a culture in which speed and daring are admired. (Witness the heavily attended annual debacle at Indianapolis where high speed collisions and a human sacrifice are an accepted and almost inevitable occurrence.) The automobile presents the depressed and frustrated individual with an opportunity to end his life in what *he* may perceive as a burst of glory. The automobile may also constitute a special enticement to the aggressive and vengeful feelings present in many would-be suicides. In an accident not only is the automobile damaged or demolished but so is any object struck by the automobile—human or otherwise. More conventional modes of suicide do not offer as dramatic an opportunity for the gratification of destructive and aggressive impulses. All this may be further complicated by the fact that even a half-hearted suicidal *gesture*, initiated while driving an automobile at

high speeds or on a crowded highway, may set in motion irrevocable forces which result in catastrophe.

Alcoholism.—The self-destructive bias of the alcoholic has been emphasized by several investigators (12, 13) as has the alcoholic's predilection for automobile accidents and serious traffic violations (3, 5, 7). In our study, alcoholism was significantly related to automobile accidents at a 1% level of confidence (Table 1). Not surprisingly, most of the alcoholics' automobile accidents (59%) occurred when the principals were intoxicated. Superficially one would be inclined to attribute this to greater and more frequent intoxication with resultant driving impairment. However, most alcoholics' suicidal attempts also occur when they are intoxicated (13, 14). Of the 9 alcoholic patients who admitted to suicidal attempts, 7 probably were intoxicated when they made their attempts. In addition to producing driving impairment, the effect of alcohol *vis-à-vis* both automobile accidents and overt suicidal attempts is probably that of neutralizing the protective function of the superego. Alcohol often precipitates acting-out behavior in persons who otherwise are quite capable of controlling their unacceptable impulses (15). Similarly, intoxication may permit the overt expression of self-destructive impulses in the same manner that it lowers superego restraints against aggressive and libidinal drives. In such instances, the automobile accident may be viewed as an expression of underlying self-destructive (and aggressive) impulses liberated by the effects of alcohol (4).

SUMMARY

Thirty alcoholic and 30 non-alcoholic male psychiatric patients were evaluated to determine past serious suicidal preoccupation or previous suicidal attempts. These data were correlated with the total number of automobile accidents for which the patient was responsible.

The 33 patients deemed to be suicidal averaged 2.70 accidents per patient whereas the 27 non-suicidal patients averaged 1.30 accidents. In the 30-patient alcoholic group, the 17 suicidal patients were responsible for 63 accidents, whereas the 13 non-suicidal patients were responsible for 24 accidents,

⁴ It should not be assumed, however, that all suicidally motivated automobile accidents are the product of unconscious processes. As noted above, one patient consciously and deliberately tried to end his life by driving a car into a solid object at high speed. A current study by the Harvard Department of Legal Medicine has revealed a number of fatal automobile accidents in which the calculated and planned suicidal intent was unmistakable (9). In addition, life insurance company actuaries have expressed concern over the disproportionately high number of fatal automobile accidents in the first year of double indemnity life insurance policies and have speculated that this may be due to "simulation of accidental death conditions by persons who actually committed suicide" (10).

yielding mean values of 3.70 and 1.77 accidents per person respectively. These differences were statistically significant.

Due to the accepted and real hazards of driving, the automobile constitutes an ideal self-injurious or self-destructive instrument, particularly for persons intent upon camouflaging their suicidal motivation from others—and from themselves. With one exception, all patients believed their traffic accidents were fortuitous.

Alcohol intoxication may be responsible for automobile accidents not only because of the resultant driving impairment, but also because of its potential for reducing the controlling and conforming function of the superego, thus releasing aggressive and self-destructive impulses which find expression in traffic "accidents."

This investigation points toward the possibility that unconscious self-destructive impulses, sometimes abetted by alcohol intoxication, are a major although covert factor in the etiology of certain automobile accidents.

SYSTEMATIC DESENSITIZATION WITH PHOBIC SCHIZOPHRENICS

R. C. COWDEN, Ph.D., AND L. I. FORD, Ph.D.¹

"Psychotic patients do not respond to this treatment and of course receive it only if misdiagnosed as neurotic"(7). Thus is dismissed without a thorough investigation, a potentially useful therapeutic technique, systematic desensitization. As King(3) has shown, psychotic patients do respond to conditioning techniques and the benefits derived therefrom do generalize to other situations.

Although the paradigm of King differs considerably from that of Wolpe they both are essentially an attempt at treatment using learning principles. Certainly, there are many patients who are confined to a mental hospital because of one primary phobic or obsessional symptom. In some cases if this symptom can be removed the patient could return to society. Admittedly, the patient would have to be able to attend to the therapeutic situation and be able to recognize and communicate to the therapist what is an anxiety-arousing stimulus. As Reynolds(5) points out, the lack of similarity between a patient's verbal and overt behavior casts doubt on his ability to perform adequately any of the patient's duties in Wolpe's technique, such as arranging the hierarchy, guiding the relaxation training, or signalling the therapist when a high level of anxiety was reached. This verbal-behavioral discrepancy has been verified elsewhere(1).

Thus, there seem to be two major stumbling blocks in using this method with schizophrenics: 1) their unreliability in picking out anxiety stimuli, and 2) their inattentiveness and lack of concentration during therapy.

The authors, having demonstrated in a laboratory situation that schizophrenics do respond to systematic desensitization(2), felt it necessary to attempt to use the technique with actual clinical symptoms. Two long-term mental patients, with well structured and encapsulated phobic reactions,

were chosen as experimental subjects. Both carried the diagnosis of paranoid schizophrenia. The methodology used was the same as used in a previous experiment(2) and, as described by Wolpe(7), and Lazovik and Lang(4). The results are presented in the form of a case report.

S1 was a 27-year-old, single, high school graduate who had served in the Marine Corps for 3 years. A survey of his clinical folder revealed that this patient began withdrawing and becoming more solitary toward the end of his military service. When he returned home he became very tense, restless, refused to work and drank excessively. He had frequent arguments with his parents. His mother became ill and was hospitalized and treated for a stroke and/or some mental disorder. The patient felt that the family blamed him for the mother's illness and as a result left home, toured the country, and, when he ran out of money, finally got a job in the midwest in electronics. Gradually he became quite hallucinated and deluded (delusions of reference, influence, persecution, etc.). Upon his return home the arguments with his family became more violent and he threatened to kill certain members.

He admitted himself to the hospital in 1956 and was diagnosed as schizophrenic reaction, paranoid type. He received a course of insulin coma treatments, with little sustained improvement, and has been treated with various tranquilizers since that time. He was seen in regular psychotherapy, off and on from 1957 to 1961, with little change shown on his part.

This patient was chosen for desensitization because he showed a clear-cut phobic reaction of being unable to talk to other people without becoming extremely panicky and frightened.

His movement in the usual type of psychotherapy had been very slow. Primarily, he appeared to be passively resistive and at times negativistic. Rarely did he speak freely for a whole interview, and this happened only when he was feeling at his best. Discussing such things as familial relations, anger, sex, etc., was quite traumatic to him. He would tremble, chain smoke, become

¹ VA Hospital, Leech Farm Rd., Pittsburgh 6, Pa.

tearful or block completely and claim that his mind was blank.

The patient was asked to participate in this experiment and he agreed. The symptom to be removed was his marked fear of talking to other people. Experimental procedure began in October of 1960 and stopped with the eighteenth session in January of 1961. Some of the items from the hierarchy are talking freely :

2. About a movie you saw.
3. About your experience to an interested and sympathetic nurse.
6. About something extremely serious in a joking manner to nurse B.
7. To a patient in canteen who looks sloppy or revolting to you.
11. About current events to someone you consider less intelligent than you.
12. About current events to someone you consider more intelligent than you.
14. About your symptoms of mental illness to your therapist.
16. About your symptoms of mental illness to the ward nurse, Miss B or Miss D.
17. About your personal difficulties to a pretty girl in a restaurant.
18. About your symptoms of mental illness and very personal difficulties to Dr. E.
19. About your very personal difficulties to your sister.
20. About your very personal difficulties such as hallucinations, delusions of persecution, racing thoughts, in group therapy.
22. About your very personal difficulties to your father.
24. To both your mother and father about your future plans or your lack of future plans.

The subject seemed to learn relaxation techniques quickly. However, his outside practice tended to be irregular. He preferred to practice while lying down, rather than while sitting. Invariably, he relaxed enough to fall asleep. Scores on Forms A and B of the Stanford Hypnotic Susceptibility Scale were both 11 out of a possible score of 12. He stated he was able to visualize the hierarchy scenes quite vividly. He refused to raise his hand if he felt disturbed ; and he reported afterward that he thought he "would wait it out"—the second presentation of the scene was not as disturbing. Fortunately, this was reported in the first desensitization session, so thereafter, the experimenter watched for be-

havioral cues of disturbance (sharp intake of breath, tensing of body, rapid breathing, swallowing, *etc.*), and then stopped the visualization.

When about half way through the hierarchy, patient, ward personnel and others who worked with the patient, reported that he was more relaxed, friendly, and much more talkative. Auditory hallucinations had ceased before the experiment. However, there were other symptoms which bothered him and these began to decrease in severity. They ceased entirely within a month or two after the last experimental session. These were unusual thoughts, vivid dreams which disturbed his sleep, and ideas of reference. He began going home on passes again. He became regular in attendance and efficient in his work assignments. Cigarette smoking decreased. In regular therapy he talked freely and at length and was able to discuss things he had not mentioned in more than 3 years.

Patient reported that he still had some difficulty in talking in a very talkative group. For example, once while home on a weekend, many relatives were there and everyone seemed to be trying to talk at the same time. Patient stated he felt overwhelmed and had to leave the room.

However, on a pass in early May he discussed with his mother and father the possibility of his coming home to live with them when discharged from the hospital. This was a very unusual bit of behavior for this patient. However, the parents refused to accept him at home. He stated that he felt very disappointed and was somewhat depressed afterwards. So far, no adverse effects have become manifest, and the patient continues to be relatively talkative. This case might well be considered a successful demonstration of the desensitization therapy with schizophrenic subjects.

S2 was a 42-year-old World War II Navy veteran. He was admitted to this hospital in 1955 with an admission diagnosis of paranoid schizophrenia, and has been hospitalized continuously since then. The symptoms present at admission were primarily ideas of reference and delusions revolving around financial matters. He felt that his wife, sister, minister, and friends were trying to take his property and money away from him.

He has been combative prior to and ever since admission. An assault upon his sister was the event that led to his present hospitalization. During the first 3 years of hospitalization he was continuously combative and was controlled in this matter only by EST. A symptom that he developed shortly after admission was difficulty in urination. This difficulty was manifested only when it was necessary for him to urinate in the presence of other people. If he was permitted to enter a booth the difficulty disappeared. He also expressed considerable concern over being sterile. He has had very little sexual experience other than with his wife, and even this has not occurred with much frequency. His records reveal that in 1958 he began to develop the symptom of being unable to leave a room without thoroughly checking to make sure he left nothing behind him. The primary thing he feared leaving behind was a letter. He told the experimenter that the worst thing he could leave behind was a letter dealing with financial matters. Also, the combativeness subsided considerably once this other symptom of checking on leaving something behind him appeared. If the checking subsided then the combative behavior would begin to occur.

He was very anxious, extremely tense and had great difficulty in relaxing. Beyond the symptom of constantly checking for fear of leaving something behind him, the patient was rational and oriented. He was able to discuss various subjects and had some insight into his illness. He realized that the reason for his continued hospitalization was his inability to leave a room without the constant checking.

This patient seemed like an ideal candidate for the technique of systematic desensitization. His symptom was a marked obsessional reaction which appeared to be amenable to hierarchy development and gradual desensitization. This treatment technique was discussed with the patient, hypnosis was described to him and he was given the choice of participating in the experiment. He was quite enthusiastic about the therapy since he himself stated that ordinary psychotherapy had been of little benefit to him. Incidentally, this man had been exposed to continuous psychotherapy since admission to the hospital.

On the Stanford Hypnotic Susceptibility Test he achieved a score of 8. Following this he was instructed in relaxation techniques and was told to practice as frequently

as he could. This patient did very little practicing of relaxation on his own time. It may well be that this patient was unable to relax by himself because of his constant need to be alert against anyone taking anything which belonged to him. Another manifestation of this patient's symptoms was the need to collect large numbers of letters which had been written to him. At times there would be as many as 20 letters on his person. He would have them tucked in his belt, inside his shirt, and in all his pockets, even in his socks.

This subject was seen for 56 sessions. The usual technique was followed, in that there was a discussion of his fear of leaving things behind: then the development of the hierarchy, and followed by relaxation training. The hierarchy is as follows, with the least anxiety creating situation as No. 1:

1. Entering a room
2. Leaving yesterday's newspaper behind
3. Leaving today's newspaper behind
4. Leaving a book
5. Leaving an advertisement received in the mail
6. Leaving a bill received in the mail
7. Leaving a pencil
8. Leaving an office
9. Leaving a picture of mother
10. Leaving a picture of the wife
11. Leaving the ward
12. Leaving the day room
13. Leaving a letter from his aunt
14. Leaving a letter from a person he hadn't seen in 10 years
15. Leaving a letter from a recent friend
16. Leaving a letter from another aunt
17. Leaving a letter from his mother
18. Leaving a letter from his wife
19. Leaving a letter from his guardian

The hierarchy was constantly manipulated and changed to fit the therapeutic situation. As described before, the items had to be made extremely specific for the patient not to respond with anxiety. Starting with session 11, assertive responses were used with the relaxation technique. The patient was requested to leave a blank sheet of paper in the room when he left. Later it was necessary for the patient to sign his name on the sheet of paper and leave it behind him. Then this was followed

by writing the name and address of his mother on a sheet of paper and leaving it in the room which was quite disturbing at first. Eventually, however, the patient got to the point where he could do this with considerable ease. Periodically, it was necessary to keep the patient hypnotized until he was out of the room because of the extreme tension and inability to make the voluntary move. Also, it was necessary at times to devote the entire session to relaxation and hypnosis because of the extreme tension and anxiety displayed by this patient.

Another unusual thing about this case is the fact that the patient was more disturbed when he had *no* letters on his person to check their presence. In other words, it appeared that the letters served as a "Jonah Rag" and were something upon which he could concentrate his anxiety. This may well fit in with the idea that the fear of leaving a letter behind him replaced the inability to urinate and the delusions about someone taking his money and property. So long as he could check on the letters, he felt the other two situations were handled. Also, the combative behavior increased when the checking decreased.

Following the 56th and last session, the patient had shown some improvement in that the combative behavior had decreased and the patient was able to leave a room when the therapist was present. However, this behavior did not generalize to other personnel. Upon completion of the experiment the patient was able to lay all his letters on the table and leave the room and walk out of the ward so long as the therapist was present.

The results with this patient were not nearly as successful as with S1. Whether this is a function of the patient's inability to pick out the anxiety stimuli and respond to it or whether it is due to his inattentiveness and lack of concentration it is difficult to say. However, from all appearances the patient was able to attend to the treatment situation and concentrate upon the scenes presented. One possibility in this case may be that the patient's symptoms serve as a terrific secondary gain to him in that it relieved him of anxiety involving other situations and concentrated it all in one area. Thus the removal of the symptom could

have resulted in overwhelming, all-pervasive anxiety which would make the patient extremely uncomfortable.

Actually this symptom may not have been anxiety-creating—that is, leaving things behind; but rather the symptom was anxiety-relieving. Removal of this symptom may actually have increased the degree of anxiety which is converse to what is required of systematic desensitization.

The results of these two cases indicate that Wolpe's psychotherapy by reciprocal inhibition can be an effective therapeutic technique with schizophrenic subjects. However, due to the marked variability found in the schizophrenic population it can be effective only with certain specific cases. This is reasonable since the term schizophrenia does not define a homogeneous population. Therefore, one should not expect a particular therapy to be effective with the entire population.

It is possible that with S2, he was unable to identify the various anxiety-creating stimuli. Rather than using the verbal report which is frequently discrepant from the actual feeling or behavior of the schizophrenic subject as shown by Cowden, Reynolds and Ford(1) we should look for more objective measures of anxiety. What is needed is a more objective method of identifying stimuli which are anxiety producing for the individual schizophrenic. For example, peripherally recorded somatic responses may be able to serve this function of anxiety indicators. This would relieve the subject of the responsibility of indicating to the therapist what is anxiety-creating and what is anxiety-reducing.

CONCLUSION

Systematic desensitization is an effective therapeutic technique for some schizophrenic subjects. This neither refutes nor supports Wolpe's statement that psychosis is due to biochemical or physiological changes. It simply reaffirms that all learned behavior can be unlearned, even with schizophrenics.

THERAPEUTIC PROCESS AND BEHAVIOR—AS OBSERVED IN PHYSICAL REHABILITATION¹

MANUEL D. ZANE, M.D.²

Psychiatrists are seeking a better understanding of what takes place between the patient and therapist to result in improved behavior(1, 2, 3). Two levels of psychotherapy are recognized. One, "deep therapy," is conducted through a prolonged and intensive process called "psychoanalysis." There is the most serious disagreement here as to what is improvement and how such change occurs(4, 5). Reports of careful studies are awaited(2). The other, "superficial therapy," is widely recognized as playing a most significant role in a person's struggle to live and to grow, but our understanding of this process is woefully insufficient and rests at present upon such inadequately validated explanatory terms as "rapport," "suggestion," "identification," "transference," "insight," *etc.* What is needed is detailed study of behavior as it changes in relation to changing therapeutic conditions so that the principles underlying such a widespread and critically significant phenomenon can be elucidated more adequately. Methodologically, patients with disturbed motor behavior particularly lend themselves to such a study at the clinical level because this aspect of behavior is readily and publicly observed and measured.

In physical medicine and rehabilitation, patients with physical handicaps whose motor performance and general functioning change markedly with therapeutic intervention can be observed. When problem patients continuously fail to learn despite apparently adequate neuromuscular capacities, they begin to exhibit reactions that are characteristic of *mental illness*, *i.e.*, their behavior is markedly inappropriate to the task being attempted and in the existing conditions they fail to learn to perform

more capably. When, after consultation and study, therapeutic conditions can be introduced which are more suited to the individual patients, they behave in a way that is typical of *mental health*, *i.e.*, they function and learn more effectively.

We may then ask this question: What occurs in successful physical rehabilitation that determines a change in the patient's behavior from that typical of mental illness to that of mental health? Hopefully, the answer to this question may delineate the common factors in therapy that influence a change in behavior and suggest some of the principles governing the relationship in physical rehabilitation and possibly in "superficial" psychotherapy.

The hypothesis offered here is that rehabilitation problems develop when a patient tries to achieve goals currently beyond him and that therapeutic intervention succeeds by focussing the patient's attention on individualized goals that are achievable and related to the prescribed goal. Thus, selective attention, regarded as critical for consciousness by William James(6) in 1890, is believed to be the key to generating more effective functioning and learning in the presence of disturbed behavior.

This hypothesis is in accord also with a contemporary conception that associates the operation of the brain with particular fields of sensory information which may vary from moment to moment with the shift of attention(7, 8). The data received centrally must be neither too much nor too little for the brain's current processing capacities(9, 10). Otherwise, stress and disorganization, which, clinically, are manifested in inappropriate and stereotyped behavior, arise and get worse as further effort, under unfavorable conditions, causes the discrepancy to widen between the patient's goals and his actions (11, 12, 13).

Therapeutic intervention controls the field of stimulation so as to maintain the cerebral organization necessary for effective behavior and learning, thereby preventing

¹ Presented in preliminary form at the Sixth International Congress on Mental Health, World Federation of Mental Health, Paris, August 30, 1961.

² Adjunct Attending Psychiatrist, Montefiore Hospital, Bronx, N. Y.; and Asst. Clinical Professor of Psychiatry, New York Medical College.

the rising stress and spiralling disorganization that accompanies continuing inability to achieve a goal (14).

This hypothesis has evolved over an 8-year period from many hundreds of observations of problem patients with all categories of motor disability. In them, measurable beneficial change resulted when goals suited to the individual's motor and psychological handicaps could be developed and introduced. Fifteen such cases are reported elsewhere (15, 16). Here, 5 abbreviated cases will be used to illustrate both the behavioral changes accompanying failure and success in physical rehabilitation and the therapeutic measures that induced constructive changes in motor function. The disability was predominantly psychologic in the first 2 cases and organic (neurologic) in the others.

1. A 53-year-old man with conversion hysteria arched backwards automatically when confronted with the slightest degree of uncertainty. This reflexive hysterical defense reaction gravely interfered with his balancing ability. There was insufficient neuromuscular pathology to explain the symptom. Very slowly, and with great difficulty, he learned during the rehabilitation program to stand in the parallel bars with hands stretched out sideways. Then, when he was asked to stand with arms extended forward, he immediately reared backwards and almost fell. With each attempt, he usually appeared tense; his mouth quivered as he spoke, his neck vessels pulsated vigorously and rapidly, perspiration beaded his forehead, and sweat stained most of his shirt. Again and again, over a period of weeks, he failed until the staff feared that he was hopeless.

As the patient found himself increasingly unable to control his involuntary reactions to the task a new approach was taken. A therapist stood in the bars in front of the patient and let the patient's forward-stretched hands just touch his. This enabled the patient to stand as directed, first with palms touching and then separated by 2 inches. If the gap was widened to 4 inches, however, the disruptive, massive hyperextension reappeared.

By letting the patient gain stability at a 2-inch, and then a 3-inch distance, he was able to learn to handle the 4-inch distance. Pursuit of such highly personalized immediate goals permitted the patient to master progressively each successive level over a 2-week period until finally he was able to stand alone with his

arms before him. Under the new conditions in that situation the rearing reaction occurred less often and was less extensive. Simultaneously, he appeared less tense and distraught.

2. A 63-year-old man, with a major diagnosis of hysteria, suffered from episodes of grossly disassociated states of consciousness including disorientation for time, place and person, and from a delusion of having "3 heads." Examination failed to reveal any neurologic or neuromuscular disturbance.

The patient regarded himself as "the calmest man, with patience for everything." He complained strongly, however, of severe pain almost perpetually in his back and particularly in his legs. As he flexed his right knee to 20 degrees he said, as he grimaced and shuddered, that the pain became terrific "like a cutting of the flesh that is in the hollow of the bone." He then stopped and straightened his leg saying that it was unbearable. He was then asked to bend his knee as much as possible and to *focus on the pain itself* and to report any change in its severity as he observed it. He volunteered that the pain had never gotten the least bit better with time—only worse—unless he straightened it out or got some medication. But to his amazement as he complied with the request, he observed the pain going through irregular phases of getting worse and better even though the knee remained flexed. Indeed, while observing himself in this way, he was able to flex his knee 90 degrees more than he could do alone in the presence of pain.

We may assume that as he focussed on the vividly envisioned "tearing" of his flesh, he reacted automatically to this image in ways that added to his pain. In turn, this whole process decreased when he shifted his attention as directed, and concentrated on measuring and reporting changes in the severity of the pain.

3. D.L., a 10-year-old boy with congenital brain damage of unknown etiology, was intelligent and had no detectable neuromuscular or sensory disorder. However, he had unusual difficulty in approaching many different kinds of new tasks. When asked to chart a graph, he said "I can't . . . I can't do remainders (*sic*) . . . I want to go . . ." and got up to leave. He was then asked to try to stay and to do what he could, no matter how poor the result might be.

As he again took up the pencil, he began to ask a host of apparently unrelated questions, started to rub his penis vigorously through his

trousers, and wrote "shit" on a piece of paper. The therapist ignored the patient's reactions, which he regarded as responses to the stress of anticipated failure, and pressed him back to the task, helping him, step by step, to organize the concept of the graph, starting with what he knew and could handle. The patient was told when he was doing better or when he was doing worse. Within 4 sessions he had learned to handle the graph problem very satisfactorily. As he learned, his disordered reactions to stress in that situation decreased and then disappeared.

The graph, by virtue of its remote and indiscriminate association with arithmetic problems, apparently evoked reactions linked to previous disturbing failures. These defensive reactions tended to interfere with performance and also to antagonize the person trying to help him. By recognizing these relationships the therapist could help to focus on the problem in such a way that constructive performance and learning resulted.

4. A 72-year-old, right-handed man with a left hemiparesis had a weakness of the right upper extremity without any detectable impairment of sensation.

The rehabilitation objective was for the patient to feed himself. As he attempted this, his hand shook wildly and he did inexplicably badly. After 3 weeks of fruitless effort, the patient was refusing to make any more such efforts and was abusing the staff. He demanded that they feed him, calling them his servants, and was widely disliked for his arrogance and uncooperativeness.

Examination then revealed for the first time that he got upset when he encountered a persisting discrepancy between what he *saw* and what he *felt*. As he tried to gather the food and carry it to his mouth, he noted that the spoon was to the left of where he felt it was. Upon bringing the spoon to where he sensed his mouth was, he saw it resting 1 inch below his chin. He said "I must be crazy," and appeared agitated at this revelation.

He was then told that his perplexing difficulty could probably be better ascribed to brain damage. He was encouraged to make new efforts with the immediate aim of trying to pick up the food *as he kept looking at it*. Slowly his ability to perform the procedure in a coordinated way improved and within a week he was able to bring the spoon to his mouth readily. His abusiveness and negativism

disappeared. Apparently, repeated effort with suitably focussed attention established new neuronal relationships between visual, kinesthetic and proprioceptive impulses which were more appropriate to the attempted action.

5. A.I., a 45-year-old woman with parkinsonism of 11 years' duration reported that for the past 3 months she had been unable to turn the door-knob to open a door. She said that other functions, such as cutting food on her plate, holding a cup, *etc.*, had also been lost abruptly and irretrievably. She remarked that she expected to end up a hopeless cripple and regarded the new loss of function as signalling imminent total loss of muscular control. She vividly visualized herself leading a wheelchair hospital existence. As she spoke in this way, she began to shake markedly and said she did not like to think about such unhappy events because it made her feel and act worse. She was then taken to the door and asked to try turning the knob. She put her hand on it and said, "I can't." No turning movement could be observed and this was called to her attention. She was surprised and said that she felt she had tried and had failed. When she made another attempt, she herself noted how little her hand rotated. With conscious effort—under visual control—she slowly turned the knob and with amazement opened the door.

After 2 weeks of practice she was enabled to do this automatically. Many other "lost" functions were similarly regained when the patient was able to focus completely on the task and to practice until she succeeded (16).

Presumably, when this patient functioned at the automatic level, the pathologic spasticity, rigidity and tremor were most pronounced. Thus, as she became obsessively taken up with depressing thoughts and feelings, most of her movements became automatic and she exhibited pathologic motor elements. When, on the other hand, she focussed predominantly on the task, she was able to learn to use still intact sensory and muscular capacities to achieve the desired action.

DISCUSSION

When a patient continues to fail in his program and acts inappropriately, he becomes concerned with an endless array of private goals as well as the designated therapeutic task. In ways typical of his personality, he becomes concerned with the growing disorder and discomfort of his body and

mind and also with his relationship to the therapist. His concept of the present automatically evokes arresting and distressing images of himself in the future. To each of these views there is a prepared defensive reaction. This changing and pyramiding conglomeration of goals and reactions sets up swarms of conflicting stimuli that overwhelm the brain's current organizing capacities. The more the patient attempts, the more scattered and ineffective he becomes.

Favorable therapeutic conditions stop the spiralling disorganization and restore the patient's capacities for functioning and learning productively by helping him act effectively (*i.e.*, to achieve what he tries to do). This desired result is accomplished 1. By focussing the patient's attention on more attainable goals that are sequentially related to the prescribed task, and 2. By providing meaningful contact in relation to which the patient can almost immediately act effectively when, in the course of the program, crises develop and disorganization becomes severe and uncontrollable.

Focussing of attention on selected goals is made possible mainly by making "effort" the immediate, readily attainable aim; by formulating new goals still connected to the distant prescribed goal that are more interesting or less dissimilar from previously accomplished ones; and by providing the patient with information that tells him when he is closer or further from the immediate objective.

Meaningful contact focusses the patient's attention upon interpersonal stimuli to which he can and does react effectively. By the same action, disorganizing stimuli associated with peripheral and conflicting goals are inhibited. Such meaningful contact can be physical, verbal or non-verbal, immediate or anticipated. The touch of a hand, the exchange of a word or glance now or in the expected future may suffice to restore the operation of healthy capabilities. An illuminating idea or a strong belief can also provide the same *organizing framework*.

Some principles governing the relationship between therapy and behavior are as follows:

1. It is probable that the immediacy and

the extent of meaningful contact needed by the patient for healthy functioning is proportional to the degree of disorganization being experienced.³

2. The more obstructive to the prescribed routine are the patient's particular physical handicap and his historically developed stereotyped reactions (*i.e.*, his psychological handicap), the more discriminating must be the selection of the next immediate goal. Sometimes, particularly when the problem is severe, these interfering factors necessitate a drastic alteration in the rate and route by which learning occurs before progress can be made.

3. When severe, disorganizing stress develops, the patient is dependent upon another person to create the conditions necessary for effective action and learning.

4. At each higher level of endeavor as the patient advances towards greater independence in his rehabilitation program, renewed disturbance of behavior is to be anticipated along with renewed need for some form of reorganizing contact.

SUMMARY

When the physically handicapped patient continuously fails to achieve his goal, a growing state of stress and disorganization reflected in ineffective and inappropriate behavior results. Therapeutic conditions favorably influence behavior by affecting the immediate goals to which the patient attends so that they are more attainable and linked to the desired goal. Under such conditions the performance of an effective action (*i.e.*, one that achieves its goal) reduces stress and restores the organization necessary for appropriate behavior and constructive learning. Thus the nature of the therapeutic conditions may determine the current balance between appropriate and inappropriate behavior and enable constructive learning to take place in the presence of severe stress.

³ Such a relationship between disorganization and contact may be a more useful explanation for the excessive dependence observed in psychotherapy than the explanations offered by prevailing psychoanalytic theories, most of which regard the current phenomenon as a re-enactment of an earlier familial relationship.

CHEMOTHERAPY COMPARED WITH ELECTROSHOCK IN 104 PATIENTS WITH RELAPSING PSYCHIATRIC DISORDERS

IRA S. ROSS, M.D.¹

The advent of electroshock brought treatment of suicidal and homicidal psychoses from the state hospital to the local community. EST has had, and continues to have, a bad press. Physicians accustomed to treating disease with no less poisonous agents than mercury, arsenic and snake venom, and surgeons accustomed to guillotine amputation alike regard EST as a brutal measure. Accustomed to the quiet of the sick room and the discipline of surgery, our colleagues tend to deny the existence of those ills which lead to self-destruction, on the one hand, and matricide and patricide on the other. The natural history of the outcome of depression is suicide and the natural history of the outcome of untreated schizophrenia is matricide and patricide. When confronted with the suffering of the mentally afflicted our colleagues, like the doctor watching Lady Macbeth who, having instigated parricide, was plagued by guilt to suicide, are inclined to say, "This disease is beyond my practice." EST is a treatment that disassembles the machinery of both the suicidal and the parenticidal processes alike. It has its usefulness in the self-destructive depressions and the parental destructive schizophrenias.

This study was undertaken in an attempt to determine the efficacy of the amine oxidase inhibitors (1-3) as compared with EST in the treatment of recurrent depressions. One hundred and two private patients who had had EST prior to the advent of the phenothiazines and the amine oxidase inhibitors were treated during relapses by these psychopharmacologic agents in the endeavor to avoid the use of EST. In some instances this was possible; in other instances it was not. It was expected that the amine oxidase inhibitors would replace EST in a large measure. This does not appear to have been clearly demonstrated. However, many schizophrenic patients in whom depressive periods previously required EST were maintained in manage-

able moods by the use of the phenothiazines in follow-up treatment and as a consequence did not suffer depressive relapses.

The private practicing psychiatrist finds it difficult to use controlled grouping of patients for a double-blind drug evaluation. However, he is in a better position for longitudinal case study than most institutional practitioners. His range of case material is likely to comprise those persons who respond to therapy, or cases that recover spontaneously. In any psychiatric care program the spontaneous recoveries tend to enhance the apparent value of the therapeutic agent. The practitioner uses the treatment that seems to him the most effective, and he is inclined to regard the agent that was administered to the last case that recovered as the best. Under the impact of pharmaceutical advertising, and his need of more effective drugs, he gives priority to the newest nostrum.

EST has so far been this author's most predictable method in the management of psychotic behavior. Gradually over the years some of the phenothiazines have come to be relied upon. The first monoamine oxidase inhibitor, iproniazid (Marsilid²), proved to be dangerously toxic. However, prior to its being withdrawn from the market a number of patients who formerly responded only to EST were treated with iproniazid. In 1959, when several other amine oxidase inhibitors were introduced (4-6), the author attempted to find one that promised to be safe.

In appraising the new agent, isocarboxazid (Marplan²), liver function was tested by determination of the serum glutamic pyruvic transaminase (SGP-T). The amine oxidase inhibitors are relatively tissue-specific in their action on brain, heart, lungs and liver. The serum glutamic oxaloacetic transaminase test (SGO-T) is more specific for cardiac tissue and the SGP-T

² Trademark of Hoffmann-La Roche Inc., Nutley, N. J.

¹ 179 Irvington Ave., South Orange, N. J.

is more specific for hepatic tissue damage. Therefore, the SGP-T was used as the transaminase test of choice. The test was customarily carried out on the tenth day of the initial 30 mg. per day dosage. Where a patient's history and physical examination gave any suspicion of liver damage, the drug was not used unless consultation with a competent internist, and a battery of liver function tests indicated it could be employed safely. After the initial tenth-day SGP-T the test was repeated at intervals of two weeks until the dosage was lowered to 10 mg. per day, after which it was done at intervals of approximately two months. One hundred and four SGP-T tests were done in connection with this study. During 3 years there were no elevated reactions, and a less rigid schedule has since been adopted. There have been no complications in the author's use of isocarboxazid.

The material for study was divided into three rough diagnostic categories (see Table 1) : I. *Schizophrenia*, including catatonic, paranoid and schizo-affective disorders. There were no simple or hebephrenic schizophrenics in the series. II. *Psychotic Depression*, including manic-depressive depressions and involutional psychotic depressions. III. *Reactive Depression*, including patients with psychoneuroses in whom the episode of depression had been sufficiently severe to need electrical or pharmacologic treatment. For the most part this group comprised the phobic reactions in which periods of depression were pronounced, as well as those obsessive compulsive neuroses in which periods of depression were accompanied by profound increase of the obsessive and compulsive symptoms.

Of the 104 cases selected for the study, 19 were eliminated either because a clear decision could not be made of the efficacy of the drug used in the relapse as compared with EST administered during the initial episode on the one hand, or because there was not a clear-cut period of remission between treatments. The 19 cases dropped included 4 schizophrenics, 8 manic-depressive depressions and 7 reactive depressions. Of the 85 cases considered useful for contrasting the efficacy of EST with pharmacologic treatment, 17 cases were schizophrenic, 45 were manic-depressive depressions and 23 reactive depressions.

Results of treatment are tabulated in Table 1. In the group of schizophrenic patients it was possible to treat successfully 6 patients in relapse with pharmacologic agents alone, whereas in 11 both EST and drugs were necessary. In the manic-depressive depressions it was possible to treat 22 of the 45 patients in relapse without the use of EST, whereas in 23 it was not possible to do without EST. Of the 23 patients with depressive reactions, 16 were treated with drugs alone, and only 7 required EST in their recurrent episodes. In this group of 23 depressive reactions most of the patients remained in contact with the physician during periods of remission, receiving group or individual psychotherapy. The efficacy of psychotherapy, or the ability of these patients to profit from it, may account for the fact that 70% of them were able to get through their relapses without EST.

As the study proceeded, it became apparent that those schizophrenic patients who were successfully treated without EST responded best to the phenothiazines (chlorpromazine and trifluoperazine). In

TABLE 1
Results of Treatment of Relapsing Disorders

PATIENTS PREVIOUSLY TREATED SUCCESSFULLY WITH EST	NO. OF CASES	SAME PATIENTS IN RELAPSE SUCCESSFULLY TREATED WITH DRUGS ALONE		PATIENTS NEEDING BOTH DRUGS AND EST FOR TREATMENT IN RELAPSE	%
Schizophrenia	17	6	35	11	65
Manic-depressive (depressed)	45	23	51	22	49
Depressive reactions	23	16	70	7	30
Total	85	45	53	40	47

the category of the psychotic depressions those patients who were successfully treated by chemotherapy alone were handled primarily by isocarboxazid (Marplan) for relief of depression and were then stabilized on lower doses of isocarboxazid and maintenance doses of trifluoperazine (Stelazine³). For the third category—the depressions attending psychoneurotic reactions—the list of drugs tried unsuccessfully is discouragingly varied. Many of the phenothiazines, meprobamate, diphenylmethane and nialamide were included. Apparently the first two categories of psychiatric ills have definite, albeit different pathologic aspects that are amenable to treatment by tangible agents of physical (electrical) and chemical (psychopharmacologic) nature. The patients in the third category seem to be best treated by psychotherapy; thus, primitive and archaic instinctual drives may be replaced by more satisfactory and more mature behavior.

COMMENT

This report is intended as a discussion in psychobiology as well as an attempt to assess the relative value of electrical and pharmacological treatment of the psychoses and neuroses. There are many variables involved in both methods and both are changing so rapidly that the drugs and the type of electrical treatment used in this study may very well be obsolete tomorrow—if they are not already.

This study clearly establishes* the fact that EST administered as an alternating current to produce a total neuronal discharge resulting in a generalized, grand mal type of convulsion is an effective agent in the treatment of schizophrenic as well as manic-depressive disorders. By producing total neuronal discharge with attendant refractoriness of the neuronal nets and reverberating circuits, EST affords the brain a return to homeostasis relatively free of the distressing driving forces exerted by latterly acquired engrams. This study also clearly establishes the fact that disordered mental states may be roughly divided into two succinct categories: the schizophrenic type of disorder that responds primarily to one

set of chemicals, the phenothiazines, and a second type, the depressive disorders that respond primarily to the amine oxidase inhibitors.

The author believes that the phenothiazines, by depressing the reticular activating mechanism, facilitate the attenuation of responses to distracting stimuli.

The ability to ignore distracting stimuli is the first prerequisite to learning and a prime requisite for rational behavior. The amine oxidase inhibitors, by blocking the metabolism of the biologic amines (serotonin, norepinephrine, *etc.*), raise the brain levels of these products of neurosecretory cells, thus acting as antidepressants. It is these neurosecretory, humoral products whose chemistry determines the mechanisms of mirth or melancholy.

Our tabulation suggests that the benefits of pharmacotherapy and EST are about equal, with 53% of the patients able to get through relapses without EST. But, as we pointed out, psychotherapy—the third factor in management of the psychiatric patient—probably played a decisive role in the patients with depressive reactions.

When we add to the picture the imponderables represented by the individual patient we get even further from the possibility of statistical statement. Some patients do not tolerate EST; in these cases chemotherapy is a valuable alternate. In other patients the phenothiazines are contraindicated because of cardiac or hepatic conditions; or an occasional patient may develop wholly unexpected side effects to a drug considered entirely safe. This throws us back upon our earlier resource, EST. And though effects of psychotherapy vary tremendously from patient to patient, we must never forget its fundamental role in long term rehabilitation.

As for the short term resources of EST and chemotherapy, their function is certainly not limited to bringing the patient through an emergency; frequently they help the patient to achieve better insight and a higher level of functioning. Since both methods have proved indispensable, it seems idle to adopt one and eliminate the other. Instead, it is more to the point to improve both methods, especially by reducing their hazards.

³ Smith Kline & French Laboratories, Philadelphia, Pa.

The hazards of chemotherapy have been pointed out in a recent article by Paul W. Wilcox(7), who is a devotee of ECT and EST adapted in the individual case. Some of his patients receive EST, others a milder, nonconvulsive form which he calls electrostimulation. The wide use of the new drugs, with their "complex and hidden side effects," he writes, "forces me to believe that my colleagues have not mastered the relatively simple methods of delicate and differential electrostimulation, combined with active psychotherapy, which make possible a high standard of therapy against which to compare the drugs."

The author, too, fears the side effects of drugs. He also has fear of injuries sustained in EST. However, if we give in to all this fear we shall be constrained to whine like the doctor in the play, "This disease is beyond my practice." By all means, let us

attempt to master the techniques of EST, let us encourage the development of safer drugs and saner psychotherapy. If in this striving we succeed in finding basic truths, we can establish psychiatry upon firmer foundations.

ABSTRACTS

THYROID IMPAIRMENT IN CHRONIC ALCOHOLICS¹

MARSHALL GOLDBERG, M.D.²

Previous studies by Richter have suggested the existence of an inverse relationship between thyroid function and voluntary alcoholic intake in rats. Accordingly, Richter has proposed that thyroid hypofunction might contribute to the abnormal craving for alcohol possessing human alcoholics. A preliminary study of the thyroid status of 33 chronic alcoholics carried out by this author in 1958 seemed to support Richter's contentions, in that 21 (64%) were found to be thyroid deficient to varying degrees. The present study was undertaken to confirm and extend these observations in a larger group of chronic alcoholics.

The group studied was composed of 82 males and 18 females, ranging from 23 to 65 years old. All were confirmed chronic alcoholics selected at random from the registry of the hospital's Alcoholism Clinic. Patients with known or suspected coronary disease or adrenal insufficiency (both relative contraindications to thyroid hormone therapy) were excluded from the study. Likewise excluded were patients with either historical, physical or laboratory evidence of liver dysfunction and those currently receiving antabuse. The methods used to assess thyroid function were the following: 1. One or more baseline protein-bound iodine (PBI) determinations, 2. The rise in the PBI 24 hours after the intramuscular injection of ten international units of a potent thyrotropic hormone preparation, 3. The electrometric recordings of the Achilles tendon reflex by the Lawson *kinemometer* apparatus, and 4. The tanned red cell agglutination procedure to detect the presence of circulating thyroglobulin antibodies.

Since it is well-documented that both acute and chronic liver disease can falsely elevate the measurements of several thyroid parameters, the response of the PBI to thyrotropic hormone was employed to help increase the accuracy of diagnosing thyroid deficiency in alcoholics with sub-clinical liver disease. Though a relatively new innovation, the Lawson *kinemometer* has proved itself to be an excellent screening test for thyroid disease and has been well over 90% accurate in distinguishing euthyroidism from even the milder degrees of hypothyroidism in several thousand patients tested.

In addition to a suggestive history and physical appearance, the following criteria were used to diagnose probable hypothyroidism: 1. A baseline PBI level below 4.0 $\mu\text{g.}$, 2. Failure of the PBI to rise over 1.0 $\mu\text{g.}$ 24 hours post-TSH, 3. A contraction phase of the Achilles reflex exceeding 280 milliseconds, and 4. Significant objective and subjective improvement regarding the signs and symptoms attributable to hypothyroidism while receiving physiological amounts of thyroid replacement (average daily dosage: 100 $\mu\text{g.}$ of triiodothyronine or 180 mg. of thyroglobulin) and *maintenance* of such improvement over a year follow-up period. Sufficient thyroid hormone to keep the Achilles reflex tracing in the vicinity of 240 milliseconds, an optimal level in most cases, was found to be the most reliable guide to adequate hormonal therapy. Moreover, a sudden, unexplained lengthening of the reflex in someone taking the rapidly-metabolized thyroid derivative, L-triiodothyronine, has proven to be a valuable adjunct for detecting if the patient omits his pills or takes them haphazardly.

RESULTS

Forty-five of the 100 chronic alcoholics tested were found to be thyroid deficient to varying degrees by the diagnostic criteria

¹ Partially supported by National Institute of Mental Health Research Grant M-4266.

² Former Research Associate, St. Vincent's Hospital Alcoholism Clinic, Worcester, Mass., and Consultant to the Massachusetts Commissioner on Alcoholism. Present address: Dept. of Medicine, University Hospitals, Madison 6, Wis.

previously mentioned, 47 patients were considered euthyroid, and the remaining 8 patients were placed in a "borderline hypothyroid" category since their test results were inconclusive. Among 90 patients tested for the presence of circulating thyroglobulin antibodies, significant antibody titers were detected in the serums of 18 of the 45 hypothyroid alcoholics (41%) and in none of the serums of euthyroid alcoholics.

DISCUSSION

Although it has been reported that alcoholic addiction is rarely encountered in patients with active thyrotoxicosis, there is no convincing evidence that the converse holds true: namely—that hypothyroid patients are frequently alcoholics. Rather, it is the author's hypothesis that the alcoholism antedates and leads to thyroid impairment in the majority of instances where the two disorders are found to co-exist. Though it remains to be proven, it is conceivable that repeated high concentrations of blood alcohol can exert a "toxic" action on the thyroid, setting into play an autoimmune-type thyroiditis which eventuates progressive thyroid deficiency. Histological studies of the thyroid glands of laboratory animals subjected to acute and chronic alcoholic poisoning have, in fact, demonstrated gross disruption of the thyroid architecture with rupture of the thyroid follicles. Taken in the light of present knowledge

concerning the pathogenesis of chronic thyroiditis, such an effect of alcohol on the thyroid could presumably trigger an autoimmune response to thyroglobulin or other thyroid antigens inappropriately released into the circulation.

Among 47 patients considered to be frank or borderline hypothyroid and treated with thyroid hormone, 16 were lost to follow-up and the remaining 31 were observed on treatment for a minimum period of one year. Twenty-four (77%) of the thyroid-treated patients seemed to derive considerable benefit from their return to a euthyroid status—both insofar as their general health and ability to control their alcoholic intake were concerned. However, the improvement shown in their drinking habits per se was likely the result of multiple therapeutic and psychological factors—in particular, the patients' own insight and motivation—and cannot be directly attributed to their hormonal therapy. It is concluded that a high incidence of hypothyroidism exists among *true* chronic alcoholics and deserves attention in their over-all management.

The treatment of the alcoholic whose laboratory tests clearly shows him to be hypothyroid logically serves to correct a potentially debilitating complication triggered by his excessive, long-term drinking, *but cannot and should not be expected to correct his underlying disease state: the abnormal craving for alcohol.*

WHY PATIENTS WITH BRAIN TUMORS COME TO A PSYCHIATRIC HOSPITAL :

A THIRTY-YEAR SURVEY¹

FREDERICK B. REMINGTON, M.D., AND SHIRLEY L. RUBERT, M.D.²

The charts of all patients discharged from the Syracuse Psychiatric Hospital with a diagnosis of "psychosis due to brain tumor" were reviewed to determine the reasons

which led to hospitalization. The frequency of this diagnosis over a 30-year period was 0.2%, with 34 patients studied. This figure, lower than the usual state hospital 2%-3%, is explained by the fact that this is exclusively a short term hospital for acutely disturbed patients. All patients were admitted for behavioral or thinking disturbances. Only 10 of the 34 cases were known to have brain tumors on admission. The

¹ Delivered at the Upstate Interhospital Conference, Syracuse, N. Y., April 1961.

² Supervising Psychiatrists, Syracuse Psychiatric Hospital, and Instructors, Dept. of Psychiatry, State University of New York, College of Medicine, Syracuse, N. Y.

remainder were hospitalized for diagnosis and treatment of presumed "functional" disorders. An accurate diagnosis was readily established whenever sensorimotor (neurological) symptoms were present, but when psychological symptoms alone presented, the patients were diagnosed as a functional problem. "Psychological" symptoms noted were: depression (8 cases), memory deficit (7 cases), combative behavior (5 cases), personality "change" (2 cases), paranoid ideas (2 cases), marked agitation (2 cases), and severe obsessional ideas (1 case). One patient had been diagnosed as having idiopathic epilepsy for years, and two others had been diagnosed before and after admission as having hebephrenic and catatonic schizophrenia. In all cases the brain tumor diagnosis was established only after a period of hospitalization during which the sensorimotor symptoms appeared. Several patients were receiving electroconvulsive or insulin shock therapy when clear cut sensorimotor symptoms first became apparent.

Since this hospital's experience in misdiagnosis is not unique, we raised the question why these cases were missed. Some physicians think the symptom triad of vomiting, headache and papilledema is present in all cases of brain tumor and do not entertain the diagnosis unless present. This leads to errors. Overemphasis of the progressive nature of tumor symptoms is a further reason for misdiagnosis, since such symptoms may be intermittent. Further causes are the doctor's lack of brain tumor awareness and failure to consider differential diagnostic possibilities. A tumor should be considered whenever a diagnosis of Alzheimer's or Pick's disease, arteriosclerotic dementia, encephalitis, parkinson's disease, cerebral vascular accident, multiple sclerosis, epilepsy or subdural hematoma is made.

What is the origin of the more purely "psychological" symptoms exhibited by these patients? Many exhibited the typical symptoms of the organic brain syndrome

resulting from tissue destruction by the tumor. More difficult to explain is the origin of psychological symptoms indistinguishable from the functional psychotic syndromes of schizophrenia or depression. Four alternate explanations exist: 1) a brain tumor may develop coincidentally in a functionally psychotic person; 2) a tumor may directly "cause" a psychological syndromes of schizophrenia or depression. psychosis in a way as yet organically unexplained; 3) the patient may develop such a functional disturbance secondary to inappropriate treatment by associates who do not understand the nature of his organic deficit (e.g., confusion or memory loss); and 4) the patient may develop a functional disturbance secondary to his subjective awareness of brain damage and loss of function. This last reason is seldom given adequate weight in explaining the origin of purely functional symptoms in patients with organic brain diseases. Depression has been long known to be precipitated by real or symbolic object loss. Since the brain damaged tumor patient has lost a significant part of his own personality, it is not surprising that depression was the leading functional symptom in our series.

Patients with brain tumors have occasionally sought psychotherapy for their psychological symptoms. The psychiatrist should make strenuous effort to diagnose and refer such patients early. Since 30%-40% of all brain tumors are benign meningiomas, often correctable by neurosurgery, early diagnosis may be lifesaving. Many writers have suggested that more frequent electroencephalograms, air studies, or angiograms be performed on psychiatric patients in order to establish diagnoses earlier. To do this is technically difficult and expensive. A constant "brain tumor consciousness" is the psychiatrist's best asset in diagnosing these patients early. He should also use appropriate psychological tests for brain damage in questionable cases.

CLINICAL NOTES

(The Clinical Notes report the findings of the authors and do not necessarily represent the opinions of the Journal.)

MULTIPLE SOMATIC COMPLAINTS AS A PRECURSOR OF SCHIZOPHRENIA

WILLIAM OFFENKRANTZ, M.D.¹

This report is part of a larger study which has attempted to specify the premorbid characteristics of patients who later become schizophrenic.

The investigation of 1000 consecutive admissions to a VA Hospital revealed that 455 had been given the diagnosis of schizophrenic reaction. Review of the military medical records of these 455 patients indicated that 144 of them had been evaluated psychiatrically while still in service, but none had been diagnosed as schizophrenic, although 131 of the group had received a different psychiatric diagnosis. Further review of the military psychiatric records of the 144 indicated that 45 had demonstrable clinical evidence of schizophrenia on the basis of recorded observations. (This judgment was based on the recorded presence of more than one of the following items: 1. Perceptual disturbances, manifested by hallucinations; 2. Thought disturbances such as delusions, gross intellectual deterioration or fragmentation of thought and speech; 3. Affective disturbances, usually inappropriateness of emotional responses; 4. Behavioral disturbances such as social withdrawal, immobility, waxy flexibility; or 5. Regression, as evidenced by incontinence or bizarre exhibitionism.)

Thus, after setting aside this group of 45 patients who were clinically schizophrenic, a final group remained, consisting of 99 patients of the original 1000 who met all the following criteria: 1. The diagnosis of schizophrenia was made at the time of admission to the VAH; 2. Their military medical records were available and indicated that they had been examined psychiatrically while in service; 3. The diag-

nosis of schizophrenia had never been made while in service, although 86 of the 99 had received a psychiatric diagnosis of some kind; and 4. The military medical records did not show gross clinical evidence of schizophrenia.

The records of these 99 patients were examined in detail, and one of the findings was that 82 of the 99 had complained of at least one bodily symptom, including 67 who had reported multiple physical complaints. Most frequent difficulties were referred, in order, to the neuromuscular, gastrointestinal, or EENT systems. In every case, whether or not an organic condition was suspected, the physician made a note indicating his impressions of a psychiatric difficulty, but never made the diagnosis of schizophrenia. Furthermore, at the time they left service, none of the patients were given a diagnosis referable to the bodily complaints previously noted.

Although it has been traditionally accepted that somatic complaints are especially prevalent among military personnel suffering from a variety of emotional disturbances, it seems quite possible that these patients with somatic complaints were demonstrating true hypochondriasis: the intense, unshakable preoccupation with nonexistent bodily illness, which has long been recognized as a precursor to severe mental illness. In 1893, Magnan(1) described the clinical characteristics of "chronic psychosis," as its long duration and steady progression through four phases. He said "the first, incubation, is characterized by . . . increasing preoccupation. . . . At that period [the patient] could be mistaken for a hypochondriac." Bleuler, in his 1923 textbook(2), declared that hypochondria is "no longer recognized as a separate disease," and noted its occurrence in a variety

¹ Assoc. Prof. of Psychiatry, University of Chicago School of Medicine, Chicago, Ill.

of "mental diseases" including dementia praecox (schizophrenia). In 1945, Fenichel (3), writing from a psychoanalytic point of view, noted that hypochondriasis "is an important complication in all psychoses, especially in their initial stages."

SUMMARY

Evidence has been presented to suggest that a significantly high proportion of a group of schizophrenic patients showed clinical evidence of a psychiatric disorder while in military service prior to the onset of the obvious schizophrenic illness. Furthermore, the evidence indicates that this

earlier disorder was characterized in part by the presence of (multiple) somatic complaints, which may well represent the classical picture of true hypochondriasis.

FUNKENSTEIN TEST IN NEWLY ADMITTED FEMALE SCHIZOPHRENICS

ROBIE T. CHILDERS, JR., M.D.¹

Since 1948 there have been numerous articles on the Funkenstein Test. Almost all articles since 1958 report findings unfavorable to the test.

One hundred seventy-two tests were administered to 48 newly admitted female schizophrenics who were placed in three groups and treated for 1 month as follows: Group A—(28 patients) 800 mg. chlorpromazine daily, Group B—(13 patients) 40 mg. trifluoperazine daily, Group C—(7 patients) 20 mg. fluphenazine daily. Those failing to show significant improvement on medication were then given a series of 15 ECTs.

Tests were administered on admission, after 2 weeks, after 4 weeks, and at 9 weeks (following ECT). After basal readings were obtained patients received epinephrine IV following which methacholine was administered subcutaneously. All tests were performed by the same examiner.

Results were determined by the methods of Funkenstein(1), Gelhorn(2), and Arneson(3), as well as a determination of the area outlined by averaging the millimeters of mercury drop below the basal level over a 20-minute period.

There was no significant difference in the

groupings of the improved vs. unimproved as ascertained by any of these four methods (Table I).

TABLE I
Results of Funkenstein Test as Determined by Four Methods

METHOD	TOTAL PATIENTS (48)	IM-PROVED (27)	UNIM-PROVED (21)
Funkenstein			
Group 1-5	38	20	18
Group 6-7	10	7	3
Gelhorn			
Group—Normal and Hyperreactive	31	19	12
Group Hyporeactive	17	8	9
Arneson			
Slight response	11	6	5
Moderate response	33	19	14
Marked response	4	2	2
Methacholine Area			
Above -26			
Range +43 to -26	23	13	10
Below -27			
Range -27 to -108	25	14	11

In this study the grouping of individual patients varied markedly having no relationship to diagnosis, medication, ECT, or state of improvement. Basal blood pressure

¹ Richmond State Hospital, Richmond, Indiana.

readings were not informative.

Our findings corroborate Braun and Rettek(4), who found the Funkenstein test offering no prognostic value in predicting the response to therapy with tranquilizers.

SUMMARY

This study of 172 Funkenstein tests administered to 48 newly admitted female schizophrenics and scored by 4 methods echoes the sentiment expressed by most authors in recent years, *i.e.*, the Funkenstein test offers little in the way of predict-

ing the treatment of choice or the prognosis that can be expected.

ACETOPHENAZINE IN AMBULATORY SCHIZOPHRENIC ADULTS

HARRY F. DARLING, M.D.¹

Seventy-five ambulatory schizophrenics were treated with acetophenazine (Tindal)² in the writer's private practice. Dosage varied between 10 and 150 mg. daily; mean dose was 30 mg. daily, but almost as many patients were on 40 mg. daily. The patients were psychotic in varying degrees and, although not all of them were committable on the basis of their symptoms, they were all psychotic enough to be beyond the prodromal or subclinical stage. It would be expected that a higher mean dose would be used if they were all acute enough to be committable.

Twenty-four cases were mixed or unclassified; 4 patients were classified as chronic undifferentiated type, and 6 as acute undifferentiated, 10 were paranoid type, 1 was schizo-affective, and 20 were catatonics. Average age was 26, and the group was about evenly divided between males and females.

Marked improvement was noted in 48 patients, moderate improvement in 10, and the remainder were minimally improved, unimproved or aggravated. Ten patients were taken off the drug as the result of drowsiness or lethargy at a dose sufficient to control their illness; these are included

in the unimproved group. Akathisia occurred in 2 patients, in 1 at 100 mg. and the other at 40 mg., and 8 patients had parkinsonian symptoms. One of the akathic patients could be controlled with an anti-parkinsonian agent and the other (taking 40 mg. daily) could not, and one parkinsonian patient was controllable. Two patients had blurring of vision, 1 had equilibrium imbalance (on 10 mg. daily), and 1 had drooling. Dry nasopharynx was complained of by 3 patients.

Of interest were the 10 paranoid patients who did well on low dosages, varying between 20 and 80 mg. daily with a mean of 40 mg. It has been the writer's personal observation over the years that paranoid schizophrenics take a high dose, at least double that of other schizophrenics. This is an observation and not based on definite statistics. It is felt that study in this area is recommended to determine if this phenothiazine is effective in lower doses than others. It seems to be much more than a coincidence.

As in previous work with this drug³ it is felt that it is smoother than other piperazines and acts more like aliphatic phenothiazines; it is a good drug to work with in this respect because blood and liver damage have not occurred. In therapeutic effec-

² The writer wishes to thank Schering Corp., and W. Wesley Herndon, M.D., for clinical supplies of acetophenazine, and their many favors.

³ Darling, H. F. : *Am. J. Psychiat.*, 118 : 358, 1961.

tiveness it is satisfactory in ambulatory schizophrenics. As in psychoneurotics the dose needed seems to be lower than that

recommended by the manufacturer, and in many cases 10 mg. tablets rather than 20 mg. are needed.

THE TREATMENT OF NON-HOSPITALIZED SCHIZOPHRENICS

GEORGE WRIGHT M.D.¹

In view of the current shortage of mental health resources, it is important to seek all possible means to avoid overburdening the present facilities and staffs. With the introduction of the phenothiazine group of drugs dramatic improvement in the psychiatric inpatient population turnover became possible. That long term treatment with such drugs is necessary is evidenced by the findings of Judah, *et al.*(1). Within 5 months of sudden cessation of therapy under inpatient conditions, Judah found it necessary to reinstitute treatment in 65% of the patients in the disturbed ward and 54.5% of the "working" patients.

To avoid similar high relapse and readmission rates among patients released from hospitals, it is all the more important that the drug of choice should be one which will control the symptoms without impairing the patient's ability to function at home, and possibly even as a wage earner. The burden of the problem of supervision of such patients tends to fall upon the family physician, with only occasional supervision by trained psychiatrists. It is important that the chosen drug be effective in a dosage with minimal side effects.

Thioridazine (Mellaril²) has been shown to be effective in the treatment of schizophrenia(2, 3). Berzel(4), reporting the absence of extrapyramidal side effects with thioridazine, emphasized the danger of such complications in ambulatory patients as "a major stress on the patient and on his family."

Following their discharge from mental health clinics, Western State and Gailor Hospitals, 37 patients with an established diagnosis of schizophrenia have been followed during the past 12 months. The

group consisted of 28 females and 9 males with an age range of 15 to 47 years. These patients received doses ranging from 50 to 300 mgm. thioridazine a day, with an average of 150 mgm. given in divided doses on a t.i.d. basis. These patients have been followed by means of progress interviews on an average of once a month. At these sessions control of symptoms and occurrence of side effects have been carefully investigated. There has been very little patient-resistance to the drug, especially with reference to the complaint of feeling physically subdued.

Routine complete blood counts and urine urobilinogen tests performed after 6 months' study were all negative. There has been no clinical evidence of toxicity with the exception of 2 cases of drowsiness, which disappeared upon lowering the dose for a few days before resuming the average dose of 50 mgm. t.i.d. Two females have experienced amenorrhea. One patient has run out of tablets on two occasions and developed hallucinatory symptoms which rapidly responded to reinstitution of medication.

Thirty-six of the 37 patients in the study continue to be satisfactorily treated at home. All 36 patients are of some service at home, and several are wage earners. Only one has required rehospitalization.

Thioridazine in moderate dosage is useful in the treatment of schizophrenic patients, following discharge from hospital. It performs the two-fold purpose of controlling the symptomatology of schizophrenia with minimal side effects while allowing the patient's progress to be followed by a physician who has no specialized training in psychiatry.

PROPHYLAXIS IN ALCOHOLICS IN THE WITHDRAWAL PERIOD

P. J. F. WALSH, M.B., D.P.M.¹

How dangerous are the convulsive seizures ("rum fits," "whisky fits") often seen in chronic alcoholics when alcohol is withdrawn? Though it has been tacitly assumed that they carry no greater risk than do convulsions in other conditions(1, 2), in some cases at least, this is not so. Elsewhere the author has described the sudden appearance of Korsakov's psychosis immediately after one or more convulsions in alcoholics who had in common a long period of very heavy drinking, signs of vitamin B deficiency and evidence of early mental deterioration, and he has suggested that the dementia may have been produced by excessive energy requirements exhausting supplies of B vitamins (especially thiamine) within cerebral neurones(3). The brain is known to need very large amounts of energy, which it obtains almost entirely by breaking down glucose through many intermediary products to carbon dioxide and water, releasing energy at each step. Vitamins of the B group act as essential co-enzymes in many of these reactions; the amount of energy produced is directly proportional to the amount of vitamins expended. During a convulsion the metabolic rate of the brain, and consequently the expenditure of B vitamins, increases up to fifty-fold. Irreparable damage is done if the metabolic processes in cerebral neurones are stopped for more than about five minutes.

Nutritional deficiencies are frequently seen in chronic alcoholics (for several reasons, of which relative and absolute dietary deficiencies are probably the most important), and it seems possible that in these patients convulsions may help to produce

the deterioration often seen in the later stages of the illness ("alcoholic deterioration"), even when the gross and obvious picture of Korsakov's psychosis or Wernicke's encephalopathy does not appear. Logically it would seem that specific measures should be taken to prevent convulsions in addition to correcting the vitamin deficiency, and for the last 8 years the author has given anticonvulsants as well as concentrated vitamin preparations as a routine (in addition to any other medicines) to all alcoholics admitted to his wards. The method used is as follows: 1. *Anticonvulsants*. A capsule containing phenytoin (Epanutin) gr. 1½ (100 mgms.) and phenobarbitone gr. ¼ (50 mgms.) is given t.i.d. for 7 days. The combination is less likely to lead to addiction (alcoholics frequently become addicted to other drugs besides alcohol), and has been shown to be more effective than either drug alone. Withdrawal fits usually occur within the first few days after alcohol has been stopped. 2. *Vitamins*. Large doses of a vitamin B complex are used, as suggested by Gould(4). An intramuscular injection of Parentrovite (high potency)² is given daily or b.i.d. for 5 to 10 days, after which a tablet of Orovite³ is given t.i.d. while the patient remains in hospital.

SUMMARY

Attention is drawn to the occasional appearance of Korsakov's psychosis immedi-

² Parentrovite (high potency) contains in each 7 ml. injection thiamine hydrochloride 250 mgms., riboflavin 4 mgms., pyridoxine hydrochloride 50 mgms., nicotinamide 160 mgms., calcium pantothenate 5 mgms., and ascorbic acid 500 mgms.

³ Orovite contains in each tablet thiamine hydrochloride 50 mgms., riboflavin 5 mgms., pyridoxine hydrochloride 5 mgms., nicotinamide 200 mgms., and ascorbic acid 100 mgms.

DISCUSSION AND STUDY OF VERTEBRAL FRACTURES IN ELECTROCONVULSIVE THERAPY

PETER D. KING, M.D.¹

Newbury and Etter(16) surveyed literature relating to vertebral fractures in convulsive therapy. They pointed out the variability in incidence of reported fractures, even when x-rays of the spine were taken before and after treatment. For example, in 8 such studies on treatment with ECT the incidence of compression fractures in 999 cases ranged from 0 to 35.4%. Newbury and Etter cite the degree of active participation of the radiologist in reporting the findings as an important factor in determining the incidence of vertebral compression fractures. This would imply some variation in the radiologists' accuracy in finding such fractures, and, if true, highlights an already existing need to compare controlled variables.

In the majority of 25 references cited by Newbury and Etter in regard to compression fractures in convulsive therapy (their references 38, 39, and 46 were not available here) almost none utilized statistical methods and few compared selected variables. One study by Dewald, Margolis, and Weiner(2) was an exception in that selected variables were compared and statistical methods applied to the results. Thus they found a "highly significant" reduction in compression fractures by the use of muscle relaxants, confirming at least three earlier reports which did not utilize tests of statistical significance(4, 15, 19). It seems safe to conclude that the use of muscle relaxants, such as succinylcholine chloride (SCC),

does reduce the incidence of compression fractures to a significant degree.

Although hardly the first to do so, I have concerned myself with the need for statistical comparison of treatment methods used in psychiatry, and some of my earlier papers reflect this concern(8-13). In one such study where two randomly selected groups were compared, one treated with the "threshold" method of ECT(1, 7, 8) showed significantly fewer compression fractures when compared with the group treated by the "glissando" method(8). Although x-rays of the spine were taken only in patients who complained of pain—perhaps missing some compression fractures (2)—nevertheless both groups were treated identically except for the variable tested, so that the finding was felt to be valid. These patients had all been treated on a Guernsey cart, lying on a firm sponge rubber pad approximately 1½ inches thick with the mouth held closed and the arms lightly restrained by an assistant.

A colleague² later more or less suggested that the sponge rubber pad under the patient flattened with the initial "start" reaction(6) of the patient during ECT, allowing more "give" for hyperflexion of the spine, and increasing the likelihood of compression fracture in the "glissando" method.

Both methods, ECT modified by succinylcholine chloride and the "threshold" method, seem to result in significantly fewer vertebral compression fractures; the former is a more complicated procedure, while the latter is somewhat more difficult to give,

¹ Asst. Prof. of Psychiatry, Neuropsychiatric Institute, UCLA Medical Center, Los Angeles, Calif.

² Richard S. Clark, M.D., Hollidaysburg, Pa.

looks to an observer as if it causes pain to the patient, and cannot be given with a simpler ECT apparatus. Accordingly it seemed practical to compare the effects of the surface on which the patient lies during the "glissando" method of ECT, surface being a variable which has not been statistically compared in previous studies on the incidence of compression fractures in ECT.

METHOD AND RESULTS

1. In a comparative study of ECT and chlorpromazine (Thorazine) in newly hospitalized schizophrenic women at Madison State Hospital (13), 42 patients were given ECT initially and 14 were given ECT after failing to respond to chlorpromazine. Of these 56 patients given ECT 43 (group X) had x-rays of the spine taken shortly after the 20th and final treatment. All 43 patients were given the "glissando" method of ECT while lying on a Guernsey cart. All conditions of treatment were the same as those in the study comparing "glissando" with "threshold" method of ECT mentioned above (8), except that instead of a sponge rubber pad, a thin woolen blanket folded to double thickness was placed under the patient on the metal surface of the Guernsey cart.

In order to have a more rigid comparison, only the 29 schizophrenic patients in the previous study (8) (group Y) were compared with group X. There was no significant difference in age between the two groups, X averaging 37.9 and Y 37.2 years. In group X there were no compression fractures, in group Y there were four—a statistically significant difference (Table 1).

2. During the study involving group X, another study comparing the efficacy of

ECT and phenelzine in depression was conducted (11). In this study 22 patients received ECT, of whom 14 had x-rays of the spine immediately after the completion of treatment (group Z). Both group X and group Z patients were treated at the same time in random order in exactly the same way using the "glissando" method with a folded blanket between the patient and the metal surface of the Guernsey cart. Aside from diagnosis, the only difference between groups X and Z was their age, group X averaging 37.9 years and group Z 55.4 years, a difference which is significant. Among the patients in group Z, 4, all over 60 years of age, had vertebral compression fractures.

This difference from group X in incidence of compression fractures is statistically significant (Table 1).

DISCUSSION

The results presented in part 1 indicate that the surface on which the patient lies during ECT is a variable influencing the probability of vertebral compression fracture. A surface which "gives" with the initial "start" reaction, such as a sponge rubber pad 1½ inches thick, apparently increases the likelihood of compression fracture to a significant degree. Since this variable remained uncontrolled and was often quite different—if even mentioned—among the studies referred to by Newbury and Etter (16), it may partly explain the wide variation in the incidence of compression fractures they cited.

In light of the findings reported in part 1, it is recommended that the patient be laid on a hard surface covered by a blanket two layers thick when ECT is given without modification by SCC. However, even when

TABLE 1
Effect of Varying Surface and Age on the Incidence of Spinal Compression Fractures in ECT

GROUP	AGE	SURFACE	VARIABLE TESTED	PATIENTS TREATED	SPINAL FRACTS.	(USING YATES' CORRECTION)	
						X ²	P
X	37.9	Rigid	("Control")	43	0	—	—
Y	37.2	Foam Rubber	Surface	29	4	(X, Y) 3.97	<.05
Z	55.4	Rigid	Age	14	4	(X, Z) 8.97	<.01

such a surface is used, among depressed patients over 60 there were 4 compression fractures, a significant difference from the younger schizophrenic patients in group X. Newbury and Etter point out that reports on the incidence of compression fractures following ECT and Metrazol therapy in relation to age are conflicting. However, some of the papers cited by Newbury and Etter showed a marked increase in compression fractures among patients over 55 (3) and 60 (14). Among four papers citing no correlation to age, the studies were made only on patients 18 to 52 (3), 21 to 60 (5), 20 to 60 (15), and 15 to 50 (18). In one study on ECT where 231 patients were treated without modification by muscle relaxants, 42 of the patients were 60 or over and did not show a greater incidence of compression fractures (2). It may be that using the rigid surface as reported above reduced the incidence of fractures in younger patients but not in the older patients. Accordingly it is recommended that such older patients who require ECT be given treatment by the "threshold" method or else treatment modified by the use of muscle relaxants, such as SCC, if compression fractures of the spine are to be kept at a minimum.

SUMMARY

No vertebral compression fractures occurred among 43 female schizophrenics treated by "glissando" ECT when they were laid on a rigid surface (group X). Four compression fractures occurred among a comparable group of patients treated on a sponge rubber pad 1½ inches thick. This difference is statistically significant. Among older female patients treated by ECT on a rigid surface, 4 compression fractures occurred—all in women over 60. This difference from group X is also statistically significant.

It is therefore recommended that older patients who require ECT be treated with the "threshold" method or else by modification with SCC in order to keep vertebral compression fractures at a minimum. Younger patients may be treated by the "glissando" method without modification by SCC with less likelihood of compression fractures provided that they are treated on a rigid surface.

INDOKLON SYMPOSIUM IN NEW ORLEANS, MARCH 1962

B. E. McLAUGHLIN, M.D.¹

Hexafluorodiethyl ether (Indoklon) has been used as a pharmacological convulsant

¹ Assoc. Professor of Psychiatry, Women's Medical College of Pennsylvania.

agent in psychiatry since the first application by Krantz, *et al.*, in September 1956. The drug was introduced at the time of the late honeymoon with the neuroleptic

agents and no major drug house had seriously undertaken to promote the clinical use of this convulsant agent. Nevertheless, a great many clinicians in the United States, Canada, England, France, Poland and Italy have independently continued psychiatric investigation of the compound. The Medical Research Foundation of Philadelphia decided to try to organize this research and set up a clearing house for various world-wide investigations in July 1958. Since that time, techniques have emerged in the laboratories of various psychiatric examiners including Kurland and his group in Baltimore, Kalinowsky and Impastato in the New York state hospital system, and Karliner and Padula at West Hill Sanitarium. Marshall, *et al.*, at Johns Hopkins have investigated its use as a potential agent in the diagnosis of epilepsy. Gunn of Toronto has started investigations as have Thigpen, *et al.*, at Augusta, Ga. Orth at Wisconsin has confirmed the extensive pharmacological work started by the Krantz group. Dolenz, *et al.*, at Tulane have started investigations of a serious nature.

In view of the sustained interest in this compound as a convulsant, and the many papers that have emerged showing its usefulness as an alternate treatment when ECT has been unsatisfactory, the Ohio Chemical Company has been persuaded to place this drug before the psychiatric world. With this in mind, the symposium was held in New Orleans on March 23rd, to which the important psychiatrists, neurologists, anesthesiologists, and pharmacologists concerned were invited. The meeting, in addition to recapitulating the history and pres-

ent status of Indoklon, emphasized the techniques which have been emerging slowly in the various laboratories. Both inhalation technique, developed by the anesthesiologists, and intravenous technique, widely adapted by various psychiatric research men, have been perfected and are available through the Ohio Chemical and Surgical Equipment Company agents.

The symposium brought out that in many cases, Indoklon therapy has been accepted by patients who were highly resistant to ECT. Perhaps, more importantly, the symposium established that Indoklon was apparently not just an alternate convulsive method to electroshock because, in some cases, patients who do not respond to electroshock respond to Indoklon, while in other cases, those who do not respond to Indoklon, respond to electroshock. This seems to open new avenues of evaluating convulsive therapy as a general psychiatric tool. The considered feeling of the entire symposium was that very little of the real nature of convulsive therapy has yet emerged in spite of its many years of clinical application.

It was the hope of the group that Indoklon would be another tool for the psychiatric world in its investigation and treatment of the total problem of mental illness.

The Medical Research Foundation of Philadelphia has prepared a film showing both inhalation and intravenous techniques of Indoklon therapy with psychiatric patients. This will soon be available in the United States and Canada.

REASON

Man has a great capacity for reasoning, but for the most part it is vain and false ; the animal has but little, but it is useful and true ; a little certainty is better than much falsehood.

—LEONARDO DA VINCI

CASE REPORTS

MANIA SEEN WITH UNDIAGNOSED CUSHING'S SYNDROME

FRANCIS J. KANE, JR., M.D., AND MARTIN H. KEELER, M.D.¹

The mental symptoms usually seen with Cushing's syndrome are those of a depressed state with paranoid and organic features(1, 2). Spontaneously occurring acute mania has not been reported before with Cushing's syndrome although mania has been seen with induced hypercortical states consequent to the use of cortisone and other compounds(3). The occurrence of mania and depression separated by a 6-year interval in an undiagnosed case of Cushing's syndrome seemed worthy of note.

B. H. was a 27-year-old white married mother of 4 children who on 12/16/55 had been admitted to the psychiatric center of North Carolina Memorial Hospital about one month after the delivery of her fourth child. She had a history of two weeks of disturbed behavior and mood, characterized by over-talkativeness, overactivity, inability to sleep and emotional swings from elation to depression. She weighed 224 pounds and had a labile hypertension (150/100). There were no signs of organicity. Prior to illness she was described as a friendly, outgoing person with a strong sense of duty, not usually given to overt expressions of anger. There was no previous history of mental illness in the patient or her family. She responded well to 8 EST treatments and was discharged. On 11/10/61 she was readmitted to the psychiatric center because of depressive symptoms of 3 months' duration. Descriptively, she showed depressed affect focused on her worsening health, suicidal ruminations, marked anorexia and marked disturbance of sleep with early morning awakening. There was no evidence of organic mental reaction. Niamid in doses of 150-300 mg. daily and supportive psychotherapy were given. Endocrinologic consultation revealed a Cushing's syndrome with virilizing features. Physical examination showed an obese (weight 240 pounds) female with moon-shaped facies, trunkal obesity, hirsutism of the face and body, male escutcheon, markedly enlarged clitoris,

purplish abdominal striae, and fat pad between the scapulae. She also had a secretion from her breasts. Amenorrhea had been present for 4 months. Blood pressure was 180/100. Metabolic studies including stimulation and depression tests of adrenocortical function were consistent with hyperfunction of the adrenal cortex. Exploratory laparotomy revealed enlarged, hyperplastic glands (weights 16 and 13 grams) which were removed completely. Follow-up studies, 3 months post-operatively, showed a weight loss of 40 pounds, loss of moon facies and hirsutism, and no deviation of mood. The patient expressed appropriate happiness over her change.

DISCUSSION

A manic reaction has not been reported before accompanying Cushing's syndrome. It has been reported in the artificially induced hypercortical states attendant upon the use of cortisone and related compounds. Use of these drugs is usually accompanied by a change of mood, most often in the direction of elevation(4). The evidence for the existence of Cushing's syndrome in this patient at the time of her manic reaction is inferential, since no specific studies were done at that time, but her clinical course seems consistent with the natural history of the illness(5). The time of onset (10-14 days postpartum) is in keeping with the usual periods before the hypercortical states mentioned above became clinically manifest. The onset of Cushing's syndrome has frequently been noted following pregnancy (6), and in several cases where the two have been associated, the Cushing's syndrome became more floridly manifest after the termination of a pregnancy(7). The changes seen in this patient after 3 of her 4 pregnancies have been similar (severe acne, weight gain, labile hypertension, change in menstrual cycle and flow, fatigue, and sensitivity to cold). Metabolic studies on these patients are rare, but the reported studies do not show significant hormonal

¹ Univ. of N. C., Chapel Hill, N. C.

variation in pregnancy(7). In addition to the chronic metabolic stresses, it is certain that the psychologic stress associated with pregnancy and with global changes in body image were probably significant in worsening the metabolic stress(8). The depressive reaction seen in this patient was unusual, since the usual signs of organic mental reaction were absent. This may reflect the absence of the disturbance in potassium metabolism and blood pH(9), since hers was primarily a virilizing endocrine disturbance.

SUMMARY

A case of mania associated with Cushing's syndrome is reported, the first such case reported. The infrequent incidence of mania with Cushing's syndrome may be related to the slowness of change usually seen with this illness which allows for development of compensating defensive processes, both psychologic and physiologic. Pregnancy, an

additional physiologic and psychologic stress, may have disrupted the patient's already precariously balanced adjustment.

INSULIN COMA THERAPY OF A PATIENT WITH A QUESTIONABLE HELLER'S DISEASE

JOSEPH MANN, M.D.¹

There are rather controversial opinions concerning the diagnosis of Heller's disease: Ford(1) feels that dementia infantilis of Heller does exist. Malamud(2) comments that the designation of Heller's disease "not only has become a waste basket diagnosis for all sorts of organic brain disease, but, more important, it has been confused with childhood schizophrenia." De Jong(3) pointed out that in 1961 a girl was demonstrated in a neuropsychiatric conference, and the neuropathologist was able to demonstrate by slides and material from a brain biopsy that this patient, having been described as an autistic child, was suffering from brain damage seen in dementia infantilis and, therefore, was considered as having had organic disease of Heller's type.

Following is a description of a 13-year-

old boy, whose illness started at the age of 3½, and who at the age of 5 in 1953 was diagnosed at N.P.I. of the University of Michigan as "either brain damage or childhood schizophrenia," and in 1956 was seen at Mayo Clinic as "childhood schizophrenia." De Jong(4), who saw the patient in May, 1961, felt that "this boy might present the picture of Heller's disease."

G.A., born July 30, 1948, was admitted to a state hospital on April 10, 1957. The father's and mother's families showed considerable psychopathology.

There are 3 older siblings. A significant item was that one sister, when the patient was 3½, married and left the home. The patient's regression began shortly after that. He was of a full-term, normal, spontaneous delivery; walked at 1 year; began to talk and said some sentences at age 2. He was adequately toilet-trained, but after the sister left home began to regress and lost his toilet-training at age 4. He became preoccupied and withdrawn at the

¹ Former Chief of Admission and Intensive Therapy Service, Ypsilanti State Hospital, Ypsilanti, Mich. Present address, Toledo, O.

age of 5, showing primitive behavior, eating with his fingers, walking or running constantly and soiling. He was admitted to the state hospital in 1957 and immediately started on chlorpromazine, 100 mg. q.i.d. He spent some time in the custody of various adolescents in the male building and grew to the point where he would shake hands, but still failed to relate to people. In January of 1958, the most persistent and difficult symptom began: vomiting. It became so severe as to require transfer to the male hospital ward, restraints and tube feedings. The patient improved and was sent to another building, but once again began the vomiting. In May 1959, reserpine was used, but without results. Compazine and phenobarbital were then instituted. In August of 1959 the child was vomiting frequently and regularly, and if left alone would vomit repeatedly. His vomiting stopped during his sleep. He also became incontinent, and ate both his vomitus and feces if not prevented. In September of 1959, still considered as schizophrenic, the patient received 12 ESTs, showing no improvement and no change in his cycles of vomiting.

In the following year the patient's condition periodically improved until finally, in September of 1960, he lost ground physically until he weighed 35 pounds. The physical findings, including complete G.I. series, were negative. At 12, he had the appearance of a child 6 years old, without secondary hair growth and with the behavior of a lower primate. He vomited immediately after each food intake, then licked this material directly from the floor, vomiting again, and again eating the vomitus. At that time he was transferred to my service, and it became obvious that if nothing was done he would die from malnutrition. Since all other means had been exhausted, we de-

cided from the standpoint of aiding nutrition as well as the possibility of modifying the "schizophrenic process" with the complication of vomiting to place him on insulin shock therapy. From November 10, 1960, until April 17, 1961, the patient received 100 treatments with insulin given in the classical way, having had 50 comas. The average dose producing a coma was between 40 and 50 units of regular insulin. The termination of coma was managed by administration of dextrose by nasal tube or, depending on severity of coma, by I.V. Under this treatment the patient's vomiting became very rare and his condition improved markedly; his weight was reported as 61 pounds in May of 1961. Emotionally, not too much change was observed.

My last professional contact with him was in June, 1961. Recently I was told that he had regressed again, showing a weight of 35 pounds, vomiting and eating his vomitus. Although only autopsy, of course, can substantiate or refute the diagnosis, the clinical picture, course and poor response to various therapies lead me to believe that this is, most likely, a case of Heller's disease. Despite the question of diagnosis, the fact remains that insulin saved and prolonged his life, even though his mental condition did not change whatsoever.

CONTROL OF ENURESIS WITH IMIPRAMINE

LESTER H. MARGOLIS, M.D.¹

Despite encouraging reports(1-3) indicating that the utilization of imipramine (Tofranil) in enuresis provides a simple and effective method of controlling this vexing and commonplace problem, this approach remains little used. The following case reports are offered as additional

evidence of the value of this compound and with the hope of stimulating further clinical trials, which, if current findings are confirmed, would result in widespread acceptance and consequent relief to the many sufferers from this condition.

1. Because of persistent enuresis, accompanied by compulsive eating and obesity, a 12½-year-old girl was referred for psycho-

¹ Asst. Clin. Prof. of Psychiatry, Univ. of Calif. Medical School, San Francisco, Calif.

therapy. Surly, petulant and uncommunicative, she was deeply concerned with her enuresis but resistant toward psychotherapy. On her first visit, imipramine, 50 mg., was prescribed nightly. This resulted in immediate cessation of bed-wetting with eventual alleviation of her compulsive eating and obesity. Despite the formidable problem present on initial referral, the symptomatic control of this patient's enuresis permitted general improvement with minimal psychotherapy. Now, after being incontinent only once in an 8-month period, she uses the drug only sporadically, such as when visiting friends overnight.

2. Refractory enuresis and behavioral difficulties prompted the referral of a 9-year-old boy. The administration of 25 mg. imipramine nightly immediately relieved his enuresis, and this was associated with an improved social and scholastic adjustment. After 3 months of control with 25 and later 10 mg. per night, placebos were substituted on alternate nights to test the need for continuation of imipramine. After a few dry nights, enuresis recurred on the nights placebos were administered. At this point, regular administration of 10 mg. imipramine was resumed and has been continued for 2 additional months, during which enuresis has been absent.

3. While undergoing psychotherapy for a profound emotional disturbance, an 8-year-old boy with almost daily enuresis, was placed on imipramine 25 mg. nightly. This has resulted in relief of the enuresis over a period of 2 months, but has had absolutely no influence on the other components of the disturbance.

The mode of action of imipramine in control of enuresis is not clearly understood. It is difficult to ascribe its effect to reduced bladder tone and irritability secondary to its anti-cholinergic action inasmuch as its enuresis relieving capacity is not shared by other compounds with comparable anti-cholinergic properties. It is unlikely that its success is a function of psychotherapy

or due to a "conditioning" process in that relief is obtained almost with the first dose and relapse occurs almost invariably with cessation of treatment. Double-blind trials utilizing placebos are lacking, but the poor response to previous therapies as opposed to the almost uniformly favorable response to imipramine argues strongly against the role of suggestion.

Although the influence of psychotherapy is apparently negligible in relieving enuresis, the removal of this distressing symptom promotes important changes in the psychotherapeutic process. Relief of this symptom is accompanied by reduction of attendant anxiety, frustration, helplessness, lack of confidence, and social ostracism. In those cases where enuresis occasions a power struggle between parent and child, with aggression and reprisal, control and rebellion, bribes and punishment, the whole structure of the battle melts away when the pivotal issue vanishes. In other cases in which enuresis is only a minor item amidst severe psychopathology, its relief contributes but little to the ultimate therapeutic outcome which must be reached by prolonged and painstaking psychotherapy.

SUMMARY

Case material presented indicates that imipramine provides a simple and effective method for the control of enuresis. On the basis of this and other reports, further clinical trials are warranted.

HISTORICAL NOTE

DESCRIPTION OF A PSYCHOTIC REACTION IN 11TH CENTURY JAPAN

JAMES D. PAGE¹

Books available in English on the history of psychiatry essentially stop at the Near East. Particularly lacking are direct references to mental disorders in early Japan. The great Japanese classic, *Genji Monogatari* (The Story of Genji), written by Murasaki Shikibu(2) during the first decade of the 11th century helps fill this historical gap by providing a primary source of data on deviant behavior among the ladies and gentlemen of the royal court. Of special interest is the gifted author's perceptive description of a psychotic reaction in a young married woman. The diagnosis of a fictional person in a novel, even when the character is presumed drawn from life, is admittedly hazardous. However, the case study reported by Murasaki has many features in common with contemporary concepts of schizophrenia. The striking resemblance to present day patients may be interpreted as additional evidence of the timelessness and ubiquity(1) of schizophrenia.

Age: At the time of her entrance in the novel, the patient had a daughter, 12 years of age, and two younger sons. It is mentioned that her illness had started several years before and her behavior had been getting progressively more peculiar and unpredictable. For some time she had stopped living with her husband as a wife in the ordinary sense of the word and had been unable to manage the household. The husband had concluded that her illness was permanent and going from bad to worse. He therefore felt justified in bringing a younger woman into the home as a mistress and homemaker. Age of onset may thus be placed in the 20's.

Temperament and Body Build: Patient was described as being by nature "very quiet and even-tempered." She seemed at times more like

a child on its best behavior than a full grown woman. She was "very lightly built." Her constant illness had accentuated her thinness and she gave an impression of "almost inconceivable fragility." She is pictured as a "pale phantom flickering across a winter night."

Slovenliness and Neglect of Personal Hygiene: In keeping with the high standards of neatness and cleanliness of the court ladies of that era, the patient had previously been tidy and well groomed. Now her hair was in a "hopeless tangle and pitifully bedraggled." Although there were many servants in the household, she allowed no one to come near her and "her room had fallen into an indescribable state of filth and disorder." On his rare visits to her quarters, the husband was appalled at the "slaternly scene that lay before him."

Impulsive, Irrational, Unpredictable Behavior: Periodically she was "desperately violent." At times she wept quietly by herself, imagining (without cause) that her husband was speaking ill of her father. For days she lay stretched out motionless upon her bed in a state of complete exhaustion. At times she "seemed barely conscious of what was going on around her." In accord with the modern concept of ambivalence, she was described as "perverse" in that her frenzy drove her to play the most "unaccountable and repulsive tricks—precisely on those whom she most wished to please." An excellent illustration is reported: the husband had caught her in a lucid moment and had taken advantage of this to discuss in a rational, reassuring manner the fact that her illness necessitated bringing another woman into the home but that he would always provide for her, look after her, and treat her kindly. The wife seemed to understand and accept the situation sensibly. When the husband started to dress for his evening visit with the other woman, she helped by scenting with perfume (as was the custom) his great riding cloak. But as he was about to put on the coat she suddenly leapt up, seized a large charcoal brazier that was used for drying damp clothes and, coming up behind, emptied it over his head.

Irresponsibility and Lack of Concern: The

¹ Professor of Psychology, Temple University, Philadelphia 22, Pa.

servants who had witnessed the above scene were terrified that the husband would "not understand"; if he thought that she was in possession of her senses and had deliberately covered him with embers and ashes he might leave her. The husband realized that it was impossible to hold her responsible; he did not blame her. Nonetheless he was angered by the look of "complete unconcern with which she surveyed the havoc she had just created." He controlled himself and, acting much as a contemporary husband would do in a similar situation, he sent out for professional help. Priests were called in to exorcise the mad woman who by the time they arrived was "cursing and raving in the most horrifying manner." After being pulled about and cudgelled by the priests for several hours, she became somewhat quieter, but next day she was still distracted and continued to rave in an unabating frenzy. Fearful that she might attempt to disfigure him or play some other sinister prank, the husband stayed out of her way for the next several days.

Explanation of Mental Illness : Reflecting

the popular belief of that era, the author of *Genji* makes casual mention of the patient being "possessed." But she has the husband explain to the wife the true nature of her illness in terms that have a modern ring.

"This continual state of grievance and jealousy in which you now live is simply due to your abandoning yourself unresistingly, morbidly to wild dreams and imaginings."

Further evidence of advanced understanding is indicated by the statement:

"He [the husband] who knew her as she ought to be could realize that her present savagery and malice were merely the result of her illness but a stranger would be terrified and disgusted."

UTOPIA

All thoughtful men agree that the present aspect of society is portentous of great changes. The only question is, whether they will be for the better or the worse. Those who believe in man's essential nobleness lean to the former view, those who believe in his essential baseness to the latter. For my part, I hold to the former opinion. *Looking Backward* was written in the belief that the Golden Age lies before us and not behind us, and is not far away. Our children will surely see it, and we, too, who are already men and women, if we deserve it by our faith and by our works.

—EDWARD BELLAMY (1888)

COMMENTS

PSYCHIATRIC IMPLICATIONS OF THE EDDINGTON LECTURE

In a 60-page booklet, reporting the fourteenth Eddington Memorial Lecture, W. H. Thorpe¹ discusses so many subjects fundamental to psychiatry that this reviewer urges everyone to read it. Prof. Thorpe is a great teacher and the author of a remarkable book on *Learning and Instinct in Animals*. He gives us new insights and tells us of his beliefs. He is known as an ethnologist, but one reads between the lines that he likes the old term "natural scientist" and would not be averse to being hailed as a great natural philosopher.

Perhaps it is significant that his official titles are "University Reader in Animal Behaviour and Fellow of Jesus College, Cambridge." Where else in the world could a natural philosopher so prosper? He gives us of his wisdom and tells us of his scientific activity and the rigorous rules that surround such research. He adds (p. 55) "But we must never allow ourselves to forget that all this activity is based first and last and all the time upon a creative imagination akin to that of the artist and mystic and that without this basis the scientific method cannot even start." And again (p. 57) "I see science as a supremely religious activity but clearly incomplete in itself. I see also the absolute necessity for belief in a spiritual world which is interpenetrating with and yet transcending what we see as the material world." And finally (p. 59) "The scientific vision must be followed wherever it leads, and the only sin against the Holy Ghost is a refusal to follow the still small voice of the scientific conscience."

Such words may surprise some scientists, but if they will but read this lecture through, and understand what Thorpe means by such words as mental, aesthetic, moral, and religious, they will see that he has made a remarkably satisfying synthesis. Many scientists have tried to make a syn-

thesis, a philosophy of life, but none has done it better, except perhaps Pierre Teilhard de Chardin in his *Phenomenon of Man*. But he took 300 pages to do it. At times Father Teilhard showed so much creative imagination that his expositions became bafflingly mystical, but he was a convinced monist, and in this differed from Thorpe who seems to accept dualism in the Sherringtonian sense. Thorpe concludes (p. 28) that the brain and the mind are continually interacting. I see nothing special, nothing unique about this. All organs of the body, and the products of their function, are continually interacting. But what is unique about the mind Thorpe states beautifully on page 16:

For me, the essential fact is that, however much or little I know of the world around me, I know my own mind at first hand and—in a sense—better than I know anything. It is my mind which experiences and interprets all that my sense organs supply, and the whole of science and every other activity of man is ultimately dependent on this basic assumption that the mind is primary in knowing. From this it follows, I believe, that mind and body are in some sense two things and that there is an external world "not-I" which is a reality, however imperfect my awareness of it may be.

I agree heartily with the first part: that I know my own mind, better than I know anything; and that the mind is primary in knowing. But I do not believe that from this it follows that mind and body are two things. Mind, I believe, is the product of the living brain in action; it is the active relationship of one neuronal aggregation with others; it is the integrative function of the central nervous system. It can no more be separated from brain than contraction can be separated from muscle, or than circulation can be separated from heart and blood vessels.

I agree that there is an external world, "not-I." It is a fact that the external world is there, even if I am not there to perceive

¹ W. H. Thorpe: *Biology, Psychology, and Belief*. Cambridge, England: Cambridge University Press, 1961.

it. According to the state of functioning of my central nervous system (that is to say, according to my state of mind) I perceive much or little of this reality, accurately or erroneously. Certainly there is the integrated personality called "I" and the external "not-I," but this fact has no pertinence to the relationship of mind to body. Taking it up here is simply changing the subject.

Of course we can classify phenomena and arrange our list so that "mind and matter are in different categories" (p. 17). But that is not an argument against the monistic point of view. Neither do I see why it raises "the problem of how to explain the interaction of each on the other." To return to my (probably too naive) analogy with contraction and muscle, I see no problem raised by thinking of the function "contraction" as a necessary and inseparable part of the living organ we call "muscle." To me "mind" and "brain" have a similar relationship. Just because the brain is an enormously complex organ, I do not have to bring in metaphysical and supernatural concepts. The philosophical principles remain the same.

Thorpe quotes and apparently admires Father Teilhard's philosophy, but he does not accept his monism. He turns rather to Sir John Eccles who believes in a *liaison* between body and mind, "that liaison with mind occurs only in special states of the matter-energy system of the cerebral cortex." Sir John apparently assumes a special property that makes this liaison possible. He points out that "it is not the nerve network itself which is in liaison with mind, but the activity of the network." Why is it not better to drop the vague concept of "liaison," and state simply: *It is not the nerve network itself which is mind, but the activity of the network?*

Eccles and Thorpe seem to consider "consciousness" and "mind" as practically synonymous terms. They cite experiments where loss of consciousness is equated with cessation of mind (p. 20, *et seq.*). In order to keep my thinking clear, it seems to me better to define *mind* as a more general function, one which includes consciousness. I would then define consciousness as that part of mind which is related to awareness of ourselves and our environment. In other

words, that part of the function of the brain which is available for introspection and apperception. From the evolutionary standpoint consciousness (thus defined) is of much later development than mind. Teilhard goes to the logical extreme of believing that *mind* is to be found in the orderliness of mineral evolution, before life appeared on earth, and that "reflective self-consciousness" developed only when man appeared, in the last few units of geological time. This development of a "reflective self-consciousness" is for Teilhard as great an evolutionary step as the development of life itself, and *mind* in this sense probably evolved in our ancestors about a million years ago. This is the part of mind most easily put out of action by drugs, anoxia and other interferences with normal metabolism. Mind and consciousness are, in all probability, made possible by the complex neuronal patterns of the cerebral cortex and the upper brainstem. In other words, they are to a certain degree physiologically localizable. Consciousness, in the sense of simple awareness, is probably found at much lower levels of the central nervous system. The innumerable functions of the brain that go on without reaching consciousness are of basic importance for life.

When Thorpe takes up the discussion of "The Minds of Animals and Men" (p. 28) he is in a field where his knowledge is encyclopedic, and his skill at clear exposition is pre-eminent. He apparently used the word *mind* to mean Teilhard's "reflective self-consciousness" or what I would call "discriminative consciousness." But this is only a matter of definition. Anyway, it is the essential thing that man has in such great measure and other animals, even the brightest, have in such small degree. He points out that recent studies of animals show strong evidence that they have a conscious affective life, but he sees no reason to believe that the behavior of lower organism, though purposive, involves conscious striving. Animals have some degree of cognition; ideation has been demonstrated, for example, a "prelinguistic number sense" that has been demonstrated in birds. In short "the difference between the mind of animals and men seems to be one of degree—the degree of abstraction that can be

achieved—rather than one of kind.” Animals excel in perception, curiosity, and exploration; they have the ability to form concepts and some show artistic activity; they can even possess a sort of faith and sometimes exhibit altruistic behavior. The main difference seems to be that man is able to free the symbol from the object so that it may be manipulated as part of an intellectual world. But even this is a matter of degree.

The last section of the book is entitled “A Biologist’s View of Man’s Nature.” Here the lecturer comes to a discussion of the relation of science, philosophy, and mysticism. He refers to sources familiar to few psychiatrists, and this reviewer believes that

most of us could benefit by extending our reading in this direction. Certainly the recent advances in biology tend to blur the lines between the ancient disciplines. Let me close with one of Thorpe’s pregnant sentences :

Although I do not of course believe that man is an animal and nothing more, yet I see the evolutionary process as the *sine qua non* of his creation in all its aspects; and where I seem to see sharp distinctions I am inclined to attribute them provisionally to the category-making activities of the mind of the biologist or philosopher concerned and to doubt whether they have their counterpart in the real world.
S. C.

FIRST CONGRESS ON MENTAL ILLNESS AND HEALTH

At the regular annual meeting of the American Medical Association, held at Chicago from June 25 to 28, announcement was made by the Council on Mental Health that the first Congress on Mental Illness and Health would be held on October 4, 5 and 6 at the Palmer House in Chicago. This is the initial Congress of its kind held by the American Medical Association, and is an important historical first. Additional significance is that the entire rank and file of the medical profession, namely, 186,000 members of the American Medical Association,

as well as the 13,000 members of the American Psychiatric Association, will now be asked to turn their attention to all those things in medical practice which relate to mental health and illness. Almost everyone will agree there is a significant segment of psychiatry which is really psychiatric medicine in a large sense, much of which can be handled in the future by all physicians, specialists, non-specialists, as well as by psychiatrists. In addition, the linking of the medical profession with allied professional personnel of other fields may benefit the efforts of all. The painstaking work of the members of the American Psychiatric Association and the joining together of many organizations in the studies of the Joint Commission on Mental Illness and Health now result in further progress and endeavor to secure the best and the most for the psychiatric patient.¹

¹ A summary of the Congress program appeared in the July 7 issue of the *Journal of the AMA*. A full text will be available on request to Lauren H. Smith, M.D., Chairman, AMA Council on Mental Health and of AMA-APA Liaison Committee for the Congress on Mental Illness and Health. For registration and hotel reservation write to Walter Wolman, Ph.D., Director, Dept. of Mental Health, AMA, 535 North Dearborn St., Chicago 10, Ill.

Lauren H. Smith, M.D.

SPECIAL REPORTS

THE FIRST PAN-AFRICAN PSYCHIATRIC CONFERENCE

ALEXANDER H. LEIGHTON, M.D., AND DOROTHEA C. LEIGHTON, M.D.¹

Called by Dr. T. Adeoye Lambo, a Conference was held at the Neuro-Psychiatric Centre, Aro Hospital, Abeokuta, Nigeria, Nov. 12-18, 1961. Its purpose was to advance the development of psychiatry in Africa through exchange of research ideas and discussion of service, training and prevention programs. The hundred members of the Conference (psychiatrists, neurologists, internists, pathologists, nurses, social workers and educators) were from all over Africa, as well as from Europe and America. The geographic span was from Mauritius to Vancouver.

The atmosphere at this meeting in the tropics near the Gulf of Guinea was one of quiet endeavor toward cooperation among professionals of different countries. Its setting, the Aro Hospital compound, occupies a square mile in the jungle about five miles from the city of Abeokuta. We were told that, being on the site of battles of the Dahomean wars a century ago, human skulls and long bones still turn up on the hospital farm and in the excavations for buildings. The Conference was an expression of man's persistent capacity for constructive effort, sitting on these precipitates of old battles, and under the shadow of new wars in a quaking continent and troubled world.

In outlining the goals of the Conference the convener, Dr. Lambo, said:

The years 1950-60 have seen amazing changes in the social, cultural and political life of Africa. Concomitant with these changes are the growth of factories, cities and towns, the rise of large business corporations, of trade unions, of new Government concerns and projects, and new problems in human relations, from the family and tribe at one end of the scale to international politics at the other.

What have these changes in our traditions

and human values done to Africa's human beings? Would it not be a good idea to do a little accounting in human value terms and, on that basis, to discuss together our national plans, our fears and hopes for the future? Might not a conference in which men of "action" and men of "thought" are brought together for common consultation on current problems lead not only to valuable discussion but also to practical results in terms of a new awareness, new experiment, new research which may be of benefit to mankind?

There has never been a time when so many ideas and methods were employed in different parts of the world in the service of mental health as is the case today. They are working concomitantly, but, unfortunately, too independently of each other. For example, our practice in Nigeria, from considerations both of experiment and expediency, has been increasingly towards putting the patients into the centre of the community. Thus in 1954 the "Village System" was instituted and this has remained as a major part of our operational study to assess the functional efficiency and the acceptability of a service.

From such an environment as the village we have been able to collect valuable clinical data and other facts of observation. Consequently, such an approach to our problem has demonstrated that it is by no means inconsistent with scientific aims, and inasmuch as it reveals the more subtle phases of the problem it may even (as it has done in our case) contribute indispensable elements to a complete description of reality. This Conference, therefore, is an effort to present a rounded picture of psychiatry in Africa—indicating its past development, its present impact on society, its future potentialities. In Africa, in particular, we are concerned with the humanistic aspect of medicine—that is, its relationship to those working in it and, more especially, those for whom its aims are designed, namely, the community at large.

At the formal opening of the Conference on Sunday afternoon, addresses were made by Dr. M. A. Majekodunmi, the Honorable Minister of Health, Federal Government of

¹ The New York Hospital, 525 East 68th Street, New York 21, N. Y.

Nigeria and other distinguished Nigerian health officers and officials of University College and University College Hospital, Ibadan. The speakers referred to the conference as a unique event in the medical history of Africa, and outlined some of the problems of modern Nigeria: the pace and character of change, the loss of tradition and custom, social maladaptation, and the existence of widespread endemic and epidemic disease. They also spoke of the multiplied hospitals and other facilities in the last decade and of plans to expand services and educational resources, to teach psychiatry to general practitioners, to do research, to promote positive mental health, and to study the traditional methods of treatment in African cultures regarding the possibility of cooperation with native healers as a means of reaching larger numbers of people with more effective treatment.

Principal K. Dike announced that University College would establish a Chair in Psychiatry during 1962 with Dr. Lambo as the first professor.

Under the chairmanship of Dr. Alexander H. Leighton the scientific sessions began on Monday morning with an inaugural address by Sir Aubrey Lewis, who extended formal greetings to the Conference from the World Health Organization. He pointed out some of the central problems of psychiatry in areas undergoing rapid change. Treating patients, training staff, and research being the three indispensable it is unwise, under the pressure of the urgent, to sacrifice any one of these for the sake of the others. Dr. Lewis said that rapid development and change do not necessarily lead to troubles, and it is necessary to try to discover and combat disturbing factors. One important requirement is the blending of the old and the new, of carrying over from traditional culture that which can have a positive force in modern life. Balance and synthesis, he said, are key concepts and he hoped that the social sciences would be given a high place in the transitional psychiatric planning.

Dr. J. R. Reese, retired Director of the World Federation of Mental Health, in his response, pointed out that most of the African psychiatrists present, *i.e.*, most of the psychiatrists in Africa, had received

their training from Sir Aubrey.

Considerable time was devoted to a series of papers on the problems of children, including studies of urbanization and delinquency, traditional child rearing practices among the Yoruba, clinical and laboratory research on diet, growth, protein deficiency, infections, *etc.*, by both African and European speakers.

Tuesday morning was concerned with neurology. The papers ranged from broad coverage of the field to several that were highly specific. Thus, we heard about modern trends in neurology, important areas for research in tropical neurology, epilepsies in Central Africa, tropical endemic neuropathies, the meningitides, and patterns of neurological disease as these are seen at University College Hospital in Ibadan. Overall it was evident that epilepsies and brain infection and their sequelae constitute major problems in Africa.

On Tuesday afternoon the topic was pharmacology. Papers were presented on the application and misapplication of psychotherapeutic drugs, on pharmacologic symptom complexes, on drugs and the depressive state, and on the need for studies to determine whether Africans react differently from Europeans to modern drugs. There was some lively discussion of the relative merits of drugs, electroshock, psychotherapy, and milieu therapy. Most speakers, however, felt that in the expanding health programs of newly developing countries drugs are of paramount importance.

On Wednesday and Thursday mornings, several papers of broad and general interest dealt with the definition of mental health, the nature of mental health in Africa, and the relationship of literacy to cultural development and to psychiatric disorder.

Following this came a series of papers on psychiatric epidemiology. After a general review of the ecology of disease in Nigeria, there was a report on the Cornell-Aro survey of psychiatric disorder in a sample of the population in the Abeokuta area, a paper on methods in epidemiological research, and a study of suicide trends in Western Nigeria.

On Friday was a general session with papers on a variety of topics including reports on depressive conditions in Dakar, the status

of psychiatry in Basutoland, the problem of urbanization in Johannesburg, traditional medicine and modern treatment in the Sudan, some general points about the place of the native healer, mental health trends and problems in Uganda, developing services in Kenya, and prospects for the future of psychiatry in Africa.

A further interesting series of reports concerned training and related topics. These included general trends in nursing education in Nigeria, the training of health personnel in mental health principles, the influence of cultural factors on nursing in Nigeria, problems of training for the integration of mental health and general health in Africa and Europe, the nature of training programs, and community treatment of mental illness.

On Friday evening Dr. E. L. Margetts (Vancouver) chaired a meeting on mental health services in Africa. Out of this came the formation of a new organization, "The Association of Psychiatrists Working in Africa."

During the week of this historic Conference many international figures in Africa and from Continental Europe, Britain, Canada and the United States built a program of great range and significance and which will serve as a blueprint for future development. It is expected that the

proceedings will be published shortly in the *West African Medical Journal*.

The members of the Conference had opportunity to visit the Aro Hospital and the Aro village where the system of patient care in a community setting is in operation; also to visit other native villages and note the contrasts in the cities of Abeokuta and Lagos.

A number of the members, selected so as to be representatives of different countries, had the privilege of meeting Sir Abubakar Tafawa Balewa, Prime Minister of the Federation of Nigeria. The interview lasted about an hour and the Prime Minister asked many questions regarding the field of psychiatry and its possible significance in the development of Nigeria.

In concluding this report, it is appropriate to say that the members of the Conference are exceedingly grateful to the Secretariat for the efficiency and thoughtfulness evident in the arrangements, and to our hosts for their warm hospitality. Especially memorable were the luncheon given by Dr. M. A. Majekodunmi, the Honorable Federal Minister of Health, a reception and cocktail party given by Dr. and Mrs. Lambo, and a farewell party given by Chief J. O. Osuntokun, the Honorable Minister of Health and Social Welfare of the Western Region.

BY ANY OTHER NAME

We cannot expect the Americans to jump from capitalism to communism, but we can assist their elected leaders in giving Americans small doses of socialism, until they suddenly awake to find they have communism.

—NIKITA KHRUSHCHEV

NEWS AND NOTES

HONOR TO PROFESSOR KAHN.—At the time of the fall convocation of Baylor University College of Medicine, Houston, Texas, September 14, 1962, a tribute will be paid to Doctor Eugen Kahn, the first Director of the Institute of Human Relations at Yale University, established in 1930, and since 1953 professor at Baylor. The September 14th ceremony honors the seventy-fifth birthday of Baylor's senior professor.

The tribute takes the form of a plaque with an inscription and a portrait of Dr. Kahn in bronze. The Eugen Kahn Medal has also been provided and will be awarded to the Resident in Psychiatry who has attained the highest standard in his work at the College of Medicine of Baylor University.

A scroll bearing the following words will be presented to Dr. Kahn :

"In recognition of your contributions and years of devoted service to Psychiatry, for your human wisdom and for the example you have set for the younger generation, we have established *THE EUGEN KAHN AWARD* to be given annually to the Resident in Psychiatry at Baylor University College of Medicine who achieves the highest standard of excellence in scholarship and service.

"By the establishment of this award, your friends and colleagues express and declare their high regard and affection for you."

COMMON NAMES FOR DRUGS.—In his recent Message on Protecting the Consumer Interest, President Kennedy spoke of the need to give drugs simple, common names and implied that, if this were done, the consumer would pay less for his medicines.

Actually, drugs are given common names at present, and every effort is made to make them simple. But there is little or no reason to think that prescribing drugs by their common names instead of brand names will result in lower drug prices. Moreover, there is substantial evidence that the general use of common names would almost certainly bring about a dangerous compromise in the quality of our medicines.

From the Presidents' statement, the consumer might easily assume two things—that no efforts are made to give drugs simple, common names in addition to their brand names and that, if this were done, drug prices would be lower. Both assumptions would be incorrect.

At present, the common names of drugs are decided by a well-thought-out system in which a number of scientific agencies, both national and international, participate. It is absolutely essential that the name adhere to basic principles of scientific nomenclature. If not, the names will be meaningless to the medical profession and to scientists generally. Usually the common name reflects the chemical make-up of the drug; and since the chemical name is often long and complicated, the common name may have to be far from simple. No one has suggested a way to avoid this difficulty.

Government pressure on the medical profession to prescribe medicines under their common names instead of their brand names is based on the theory that different versions of the same drug, produced by different companies, are of equal quality. *It would be hard to find a more dangerous fallacy.*

Several studies of the subject have revealed that two drugs having the same active ingredients may affect patients in different ways. "Indiscriminate changing of brands may actually become a life or death matter," according to Dr. Eino Nelson, of the University of California Medical Center of San Francisco.

SCHIZOPHRENIA RESEARCH SUPPORTED BY SCOTTISH RITE FREEMASONRY.—During the past 27 years through the National Association for Mental Health the 33rd Degree Scottish Rite Freemasonry, U. S. A., Northern jurisdiction, has made grants toward investigating the nature and causes of this the most prevalent of all mental diseases.

The research grants approved in 1961 amounted to \$124,500 for 26 separate projects and 11 student stipends. This brings the total amount contributed to date by the

Scottish Rite to schizophrenia studies to more than \$1,750,000.

ASSOCIATION FOR THE ADVANCEMENT OF PSYCHOANALYSIS.—Officers elected at annual meeting, April 26, 1962, for 1962-63: President: Jack L. Rubins, M.D.; Vice-President: Joseph Zimmerman, M.D.; Secretary: Melvin Boigon, M.D.; Treasurer: Albert L. Deutsch, M.D.; and Councillor: Frederick A. Weiss, M.D.

NORTH PACIFIC SOCIETY OF NEUROLOGY AND PSYCHIATRY.—The annual meeting of the Society was held in Portland, Ore., on April 5-7, 1962. The following officers will serve for the year 1962-1963: President: Robert M. Rankin, M.D.; President-elect: R. L. Whitman, M.D.; Secretary-Treasurer: Thomas H. Holmes, M.D.; Past-President: Robert S. Dow, M.D.; Executive Committee: Edward K. Kloos, M.D.; Wallace Lindahl, M.D.; Henry C. Zeldowicz, M.D.

NORTHERN INDIANA PSYCHIATRIC SOCIETY.—The following are new officers elected to the Society for the year 1962-63: President: John U. Keating, M.D.; President-elect: Theodore A. Hill, M.D.; Vice-president: August J. Dian, M.D.; Treasurer: Richard L. Shriner, M.D.; Secretary: Hans Meyer, M.D.; Counselor: H. E. Salsburg, M.D.; Delegate: Grant E. Metcalfe, M.D.; Alternate Delegate: Theodore A. Hill, M.D.; and Newsletter: Hans Meyer, M.D.

DR. HASSAN AZIMA.—Dr. Azima, Associate Professor of Psychiatry at McGill University and an Associate Psychiatrist at the Royal Victoria Hospital, and a member of the staff of the Allan Memorial Institute of Psychiatry, died at the Royal Victoria Hospital June 25, 1962. His career has been brilliant and for a man 39 years old, his accomplishments have been distinguished.

Born in Tehran, Iran in 1922, he took his Bachelor of Arts at the University of California and his M.D. at the University

of Kansas in 1948. He obtained the Diploma in Psychiatry at the University of Paris in 1953, and then at McGill University he received both a Diploma in Psychiatry and later his M.Sc. in Psychiatry.

In Paris, in the very beginning he was profoundly interested in the philosophical premises of psychiatry. With Jean Delay, he wrote on Homeostasis in Schizophrenia, and published papers dealing with Consciousness and the Body Scheme in States of Sensory Limitation. He took note of the rapidly emerging field of psychopharmacology and at McGill he founded one of the earliest sections in psychopharmacology.

He had an adventurous and inquiring mind and there appeared many reports of special journeys into other fields: occupational therapy, neurophysiology, and anacitic therapy. Because of his scholarly studies, he was in great demand. He contributed to research projects and no less than eight books contain chapters which he wrote. At the time of his death he was preparing large scale research into regression and the understanding of interpretation.

Dr. Azima's work was an inspiration to his colleagues, and his courage during the final stages of his illness won the admiration of all who knew him.

QUACKERY.—The American Medical Association published recently a 15-page booklet titled "Beware of 'Health' Quacks." This booklet is based to a great extent on papers read at the First National Congress on Medical Quackery, co-sponsored last fall by the A.M.A. and the Food and Drug Administration. It may be obtained by writing to the A.M.A. Dept. of Investigation, 535 N. Dearborn, Chicago 10, Ill., for 5¢ per copy.

SOCIETY FOR PSYCHOPHYSIOLOGICAL RESEARCH.—The annual meeting of the Society will be held October 13-14, 1962, at Cherry Creek Inn, 600 South Colorado Boulevard, Denver, Colo.

Scientists working in areas related to psychophysiology are invited. Obtain reservations by writing Dr. Sydney G. Margolin, Director, Dept. of Psychophysiology, Uni-

versity of Colorado, School of Medicine, Denver 20, Colo. Rooms are single at \$10.00 and double at \$14.00.

MEDICAL HYPNOSIS.—A graduate course in medical hypnosis will be given for physicians and dentists by the University of Pennsylvania Graduate School in Medicine. It will be a 6-month course beginning October 13, 1962. Sessions will be held at the Institute of the Pennsylvania Hospital, 11 North 49th Street, Philadelphia.

Dr. Lauren H. Smith, Professor of Psychiatry and Chairman of the American Medical Association on Mental Health, will head the teaching staff.

AMERICAN PSYCHOSOMATIC SOCIETY.—The 20th annual meeting of the Society will be held at Chalfonte-Haddon Hall in Atlantic City on April 27 and 28, 1963.

The Program Committee invites interested persons both to attend the meeting and to submit abstracts of original work for consideration for presentation. Accepted abstracts will be printed and circulated to the membership prior to the meeting, and will be available at a minimal price at the meeting itself.

Abstracts should be submitted, in 10 copies, by December 1, 1962. Please address the Chairman, Julius B. Richmond, M.D., at 265 Nassau Rd., Roosevelt, N. Y.

DIRECTORY OF PSYCHIATRIC SERVICES.—The New York City Community Mental Health Board published recently a 20-page, pocket-sized directory, titled "Psychiatric Services for Residents of New York 1962." The booklet gives the name, address, telephone number, and other appropriate information of over 180 governmental, voluntary and proprietary hospitals and clinics offering psychiatric services to residents of New York. This reference book is available without charge from the New York City Community Mental Health Board, 93 Worth Street, New York 13, N. Y.

SOUTHERN PSYCHIATRIC ASSOCIATION.—The Council met in Toronto last month.

Ham Ford, Chairman of the Program Committee, and Ivan Bruce, Chairman of the Arrangements Committee, were there. We are all used to Texas tall tales, but the scientific program and the entertainment promise to be at least as stimulating and enjoyable as ever. The annual meeting will be at the Galvez Hotel in Galveston October 7-9. President Harris and his committees are bent on making the meeting a whopping success. It is not too soon to make reservations directly with the hotel.

It was tragic news that Dr. John W. Bick of New Orleans died April 20 of a coronary. He will be greatly missed.

The Board of Regents, who constitute the Membership Committee, insist that membership applications be made on the new forms which were instituted several years ago. If new members are to be recommended and the newer application blanks are not on hand, please write to the Secretary for them.

At the Council Meeting there was some discussion about the Constitution and By-Laws and possible need for more changes.

Sullivan G. Bedell, M.D.,

Secretary-Treasurer.

THE AMERICAN NEUROLOGICAL ASSOCIATION.—The 87th annual meeting of the Association was held in Atlantic City, N. J. June 18-20, 1962, and attended by 660 members and guests; 39 scientific papers were presented.

A special tribute to the late Dr. Harold G. Wolff, Past President of the Association, was prepared by Dr. Stanley Cobb. Dr. Cobb was also the recipient of the Jacoby Award presented tri-annually by the Association to a member who has performed especially meritorious experimental work in the field of neurology.

The 88th annual meeting will be held on June 10-12, 1963 at the Claridge Hotel, Atlantic City.

The newly elected officers: President—Charles D. Aring; President-Elect—Richard B. Richter; 1st Vice-President—Morris B. Bender; 2nd Vice-President—Knox Finley; Secretary-Treasurer—Melvin D. Yahr; Assistant Secretary—Clark H. Millikan; Editor of the Transactions—Melvin D. Yahr; Elect-

ed to Council for 5 years—James L. O'Leary ; Elected to Council for 2 years—Thomas Farmer ; Representative to American Board of Psychiatry and Neurology—Sidney Carter ; Elected to Honorary Membership—Macdonald Critchley, London, Eng.

THE NEW YORK SCHOOL OF SOCIAL WORK.

—Dean DelliQuadri of the New York School of Social Work, Columbia University, has announced the appointment of Dr. George H. Wiedeman, a graduate from the University of Prague, to the Marion E. Kenworthy Chair in Psychiatry at the School.

The Marion E. Kenworthy Professorial Chair in Psychiatry was founded in 1956 in recognition of Dr. Kenworthy's 36 years of distinguished and dedicated service on the New York School faculty.

AMERICAN ASSOCIATION OF NEUROPATHOLOGISTS, INC.

—At the 37th annual meeting of the Association, the following members were elected to serve as officers for the current year: Leon Roizin, M.D.—President; Martin Netsky, M.D.—President-Elect; Walter Bruetsch, M.D.—Vice-President; Irwin Feigin, M.D.—Secretary-Treasurer; Humberto Cravioto, M.D.—Asst. Secretary-Treasurer.

THE SOCIETY FOR THE SCIENTIFIC STUDY OF SEX.

—The fifth annual meeting of the society will be held at 9:30 a.m. on Saturday, October 20, 1962 in the Barbizon Plaza Hotel, 106 Central Park South, New York City. The topic for the morning session is "New Concepts in Sex Education," Chairman, Milton I. Levine, M.D. The topic for the afternoon session is "Prostitution," Robert V. Sherwin, LL.B., Chairman.

ANNUAL MEETING AMERICAN ASSOCIATION ON MENTAL DEFICIENCY.

—The 86th annual meeting of the Association was held at the Statler Hilton Hotel, New York City, May 1-5, 1962. The attendance constituted a record with over 1400 registrations.

The officers for the Association for the forthcoming year are: President—William Sloan, Ph.D.; Vice-Presidents: Psychology

—Rick F. Heber, Ph.D.; Education—Robert L. Erdman, Ed.D.; Administration—J. Thomas McIntire, A.B.; Social Work—Marguerite J. Hastings, M.S.S.; and Medicine—Isaac J. Wolfson, M.D. Glenn E. Milligan, Ed.D., appointed to the office of Executive Director, took over his duties on a full time basis June 1, 1962.

At the Saturday luncheon, Dr. G. S. Stevenson, President, World Federation for Mental Health, spoke on international progress in the field of mental retardation.

The 1963 meeting of the Association will be held at the Portland-Hilton Hotel, Portland, Ore., May 21-25.

PENN FOUNDATION FOR MENTAL HEALTH.

—In June 1962 the Penn Foundation dedicated the new Day Care Center at Sellersville, Pa. for which planning had long been under way. Among those in attendance was Dr. Daniel Blain, Commissioner of Mental Health for the State of California and formerly Medical Director of the American Psychiatric Association at its central office in Washington. He had been identified with the development of this special service from the beginning. Dr. Kenneth Appel, head of the Dept. of Psychiatry, University of Pennsylvania Medical School, also spoke very appreciatively of the importance of the new center of which Dr. Norman Loux will be in charge.

UNIVERSITY OF CINCINNATI MEDICAL CENTER.

—The National Institutes of Health (NIH) will assist the University of Cincinnati Medical Center in launching a training program in which psychiatrists will help their colleagues in medicine and surgery in dealing with mental problems they meet in their practice and in carrying on preventive work.

Dr. Maurice Levine, professor and director of the department of psychiatry in the university's College of Medicine, has announced the university has received \$150,000 from the NIH to back the program for 5 years.

Dr. W. Donald Ross, professor in Dr. *Levine's department, is director of the training program.

BOOK REVIEWS

HENDERSON AND GILLESPIE'S TEXTBOOK OF PSYCHIATRY. 9th Ed. Revised by Sir David Henderson, and Ivor R. C. Batchelor. (London, New York, Toronto: Oxford University Press, 1962, pp. 578 incl. index and bibliog. 21s. (U.K.).)

Henderson and Gillespie has been a standard English textbook for many years. The first edition appeared in 1927. While in subsequent editions it has kept pace with new developments, it has maintained an eclectic and wholesomely conservative point of view. This is what makes it so safe a guide for students at a time when the winds of doctrine sweep in so many contrary directions.

Dr. Henderson worked for a considerable period with Adolf Meyer at Johns Hopkins University, and to his memory he dedicates the book. He pays due respect to Meyerian philosophy and what has been called his "Common Sense Psychiatry," and speaks of "reaction-types" rather than "mental diseases."

A valuable new chapter in this edition deals with Psychiatry in General Medicine and should be pondered by physician and medical student alike. It shows that many situations which in a narrow sense are strictly psychiatric are simply a part of general medicine and which the medical practitioner should be qualified to handle. Sir David refers to the vast number of cases of minor psychiatric disorders, or, could we say, of persons who seem to think that they ought to consult a psychiatrist, while to one of an earlier generation that idea would never have occurred. He suggests that the tremendous increase in means of communication (TV, etc.) may be one cause of pathogenic social unrest. He does not mention the item of propaganda, not to say advertising, arising within the field of psychiatry itself, sometimes possibly concealed in aims to "educate the public," that may make us "too health-conscious" (or too unhealth-conscious).

Under various physical therapies the authors give thorough consideration to the question of frontal leucotomy, an operation used so freely, sometimes almost recklessly for some years following its introduction, but now largely discarded in the United States. Under the heading Present Position the authors state: "Undoubtedly much relief of human suffering and important advances in our understanding of frontal lobe anatomy and function were brought about by the operation of leucotomy.

But the indications for its use have in the past five years been much reduced with the introduction of new drug therapies . . . Probably the main indication for leucotomy now is for the relief of cases of obsessional neurosis, where there have been many years of suffering and relief cannot be brought in any other way."

This ninth edition of Henderson and Gillespie has been thoroughly revised throughout and many chapters have been rewritten. It encourages a constant critical outlook on the part of its readers. It continues to "emphasize the paramount importance of the psychological factor . . . in influencing every type of illness, bodily or mental."

We miss the numerous and carefully recorded case histories, appearing in previous editions, that brought vividly before the reader the conditions described. But those were the patients of other days: their clinical traits would hardly look the same today. They have all vanished from the text.

This work takes its place in the line of great textbooks. It perpetuates its own tradition and is the safe guide it has always been.

C. B. F.

THE FUTURE OF MANKIND. By Karl Jaspers. (Chicago: University of Chicago Press, 1961, pp. xii + 342. \$5.95.)

The German title of this book was *Die Atombombe und die Zukunft des Menschen*, and that is what this magnificent book, by far and away the best that has been written on the subject, is about. Karl Jaspers, as readers of this Journal will know, was originally a practicing psychiatrist of great distinction. He is now the world's leading philosopher, the chair in which subject he has held at Heidelberg since 1928, and of which he was deprived by Hitler in 1937, and in which he was once more reinstated in 1945. The author of the three-volume *Philosophie*, *Man in the Modern Age*, *The Origin and Goal of History*, *Reason and Existence*, and *Way to Wisdom*, with the publication of *The Future of Mankind* Jaspers magnificently caps a triumphantly noble life of labor in behalf of mankind. Like Bertrand Russell, Jaspers is no mere desk philosopher, but a man who believes that the meaning of words lies in the action they produce, and to that dictum he fully lives up. *The Future of Mankind* presents a pellucidly clear analysis of the

condition of contemporary man in the face of intimations of impending doom.

Jaspers is a realist, and has no use whatever for namby-pamby approaches or quick and superficial nostrums in dealing with the threats, not simply the threat, of annihilation which are everywhere about us. *The Future of Mankind* is an inspired book, written not with prophetic fervor but with the calm and telling reasonableness of a profoundly well-informed and insightful thinker and man of action. Every word is made to tell. I have seldom, if ever, read a book so epigrammatic, closely reasoned, and closely written. It is a book of the greatest power, and the publishers do right to call it momentous. It is a momentous book, and it is one about which one need not fear to pull out all the stops, and say that it ought to be required reading for everyone, and especially for every reader of this Journal.

Someone has defined an optimist in the modern age as one who believes the future is uncertain. It is a realistic definition, but there need be no question as to whether the future has a future, if men will do what requires to be done. The helplessness and resignation which so many men have fallen into is a consequence of the despair which one blunder after another has followed with seeming inevitability. But as Jaspers shows, with the new understandings that are possible, with the new political and suprapolitical ideals that are necessary if the challenges with which we are confronted are to be successfully met, there is more than a hope that we may yet triumphantly emerge from the slough of despond into which we have fallen. But first, foremost, and finally, it is the individual upon whom the main responsibility for manning the pumps must fall if the ship is to be saved from sinking.

In 1958 Jaspers was awarded the German Peace Prize for his noble book. He ought to be awarded the Nobel Prize for Peace. He certainly has my vote, and I am sure he will have the vote of everyone who reads his book—and it should be the moral obligation of everyone to read it.

ASHLEY MONTAGU, Ph.D.,
Princeton, N. J.

THE CHEMICAL BASIS OF CLINICAL PSYCHIATRY. By A. Hoffer, and Humphry Osmond.
(Springfield: Charles C Thomas, 1960, pp. 277. \$8.50.)

This book presents the full array of data supporting Hoffer's theories on the chemical basis of psychoses. The theory proposes that anxiety, depression, and the thought disturbances associated with schizophrenia represent toxic states

induced by various substances related to epinephrine—especially adrenochrome and adrenolutin. The authors believe that in schizophrenia the transformation of adrenochrome into leucadrenochrome is inhibited, so that excessive production of adrenolutin, a psychotogenic substance, results. Since adrenochrome is an evanescent substance, simple determinations of its plasma levels are inconclusive: the experimental validation of the theory is thus dependent on differential cerebrospinal fluid-plasma ratios, tolerance tests, *in vitro* conversion rates and numerous inferences and analogies that would require computers for adequate statistical treatment. The present reviewer does not feel competent to evaluate the biochemical aspect of the work. One would welcome more specific reference to the clinical subgroups of schizophrenic subjects with whom the experimental work was done. Many of the tabulations involved very small samples, individual anecdotal case reports are adduced, in some instances the number of cases upon which conclusions are based is not mentioned, and some of the analogies and inferences seem tenuous. So bold and significant an hypothesis would perhaps gain strength from more self-criticism, and there should be a fuller consideration of adverse and incompatible data available in the literature.

In spite of these considerations one leaves the book with the feeling that something of importance is involved that merits careful attention. Comprehensive theories are much needed in this field, and the authors must be commended for pursuing theirs with tireless experimental zeal.

JOSEPH WORTIS, M.D.,
Brooklyn Jewish Hospital,
New York.

HEILPAEDAGOGISCHE PSYCHOLOGIE. (The Psychology of Remedial Education.) Vol. I, Second Revised Edition. By Paul Moor.
(Bern and Stuttgart: Verlag Hans Huber, 1960, pp. 326.)

Under Remedial Education the author understands the bringing up of children with some mental deficit, such as the mentally deficient, deaf-mutes, the psychopathic and the neglected. It surveys various "aspects" of the problem: the vital aspect (William Stern, Alfred Adler); the technical aspect (Pavlov, Watson, Koehler, Dewey, Freud); the moral aspect (Kuenkel, Haeblerlin); the spiritual aspect (Sprangler, Hartmann, Jaspers) and the aspect of educational restraint (Jung, Klages, Haeblerlin, Binswanger).

The greater part of the book is dedicated to

the phenomenon of "halt," its absence and relation to stability and steadfastness of behavior. A person without internal "halt" is deprived of principles and backbone and all his bearings, attitude and forms of behavior are unpredictable.

Throughout this interesting book great emphasis is laid on emotional support and guidance and the application of various educational theories and methods in the efforts to afford a measure of restoration to a deficient personality.

HIRSCH L. GORDON, M.D.,
New York, N. Y.

PSYCHIATRY, VOLUME I: PRINCIPLES. By E. Eduardo Krapf, M.D. (New York: Grune & Stratton, 1961, pp. x + 244. \$6.50.)

The author of this small volume is professor of clinical psychiatry at the University of Buenos Aires and chief of Mental Health, World Health Organization, Geneva. The subject is presented in two parts. Part I is called "Personology," a term not commonly used, which deals with the principles of structure and function of the nervous system, including the hypothalamus, thalamus and the cerebral cortex; with the organization of the "Psyche" including the sphere of ideals and the psychodynamics of the id, the ego, reality, and various needs and desires of the person. This part of the text includes also a description of the dynamics of behavior integration and stages of personality development.

Part II presents the semiogenetic, and pathogenetic approach to nosology. In the section on diagnosis there is a systematic history-taking procedure and instructions for the examination of the physical and mental systems. A final section outlines the individual, social and prevention aspects and procedures for therapy. There is a fairly comprehensive bibliography.

The author emphasizes that this is not offered to serve as a text book in the ordinary sense of the term, but is intended to present the conceptual foundations of various approaches to psychiatric problems. He describes the multidimensional approach to psychiatry as a foundation for practice and teaching. In keeping with the present fashion in psychiatry the material is based on the integration of general medical and psychological phenomena, utilizing recent concepts in neurophysiology and dynamic psychology.

The parts of the nervous system and other illustrations are in the form of schematic drawings which should be a useful orientation for students and those preparing for specialty ex-

aminations.

NOLAN D. C. LEWIS, M.D.,
Princeton, N. J.

FRONTIERS IN GENERAL HOSPITAL PSYCHIATRY. Ed. by Louis Linn, M.D. (New York: International Universities Press, 1961, pp. 481. \$10.00.)

To mark the World Mental Health Year, 1960, Dr. Louis Linn (Mt. Sinai Hospital, New York) has compiled observations from 44 workers in general hospital psychiatry throughout the world. These frontiersmen are, for the most part, settling new territory in a rapidly expanding province. The worldwide extent of the frontier is indicated by the sources of contributions which include Austria, West Germany, Great Britain, United States of America, France, Canada, Italy, Switzerland, Nigeria, Japan, Holland, Virgin Islands, Denmark, and Ruanda-Urundi, Africa.

The editor has divided the contributions into four parts: 1. Administration, 2. Patient Care, 3. The Impact on Medical Care, and 4. Some Developments in the World Scene. The result is an encyclopedic survey with close-up and firsthand reporting from most of the important outposts. The material is heterogeneous, often descriptive, sometimes narrative and always interesting. It is the story of an immigration and a settlement that is now far-flung. Psychiatric principles and practice have made their entry on a global scale and the frontiers are now within the general hospital walls. The fashioning of physical and chemical treatments, of psychotherapy and of the adaptation of group and social instrumentation is the modern story that is reported here.

This important book is of general as well as special interest. It can be recommended strongly to all psychiatrists and social scientists, to all physicians and surgeons and to all hospital administrators. It is the best account of modern general hospital psychiatry that I have read.

ALLAN WALTERS, M.D.,
University of Toronto.

HUMAN FACTORS IN JET AND SPACE TRAVEL. Edited by S. B. Sells, Ph.D., and Charles A. Berry, M.D. (New York: Ronald Press Co., 1961.)

This book proposes to consolidate the available information concerning the functioning of humans in jet and space environments in order that (a) interested persons of many disciplines

may better understand the problems involved, (b) physicians may have a compact reference to assist them in their preventive and therapeutic dealings with these problems, and (c) students may be provided with information that will aid them in their career decisions. There is much within the covers that will contribute to one or more of these objectives, although the organization of this material detracts from its usefulness.

There are 14 chapters, each written by a different person with one exception; the editors, in addition to contributing a separate chapter apiece, have also joined forces to produce a third. Eight of the authors are doctors of medicine, three are psychologists, one is a physiologist, and one is an engineer. From another viewpoint, eight of the authors are with the U. S. Air Force, four are with aviation companies closely associated with the Air Force, and the U. S. Navy provides a single representative. Although one would expect the Air Force to be heavily endowed with competence in regard to jet and space travel, it is believed that the monopoly indicated in this book does not adequately reflect the available talent in other U. S. laboratories, both military and civilian, especially in the areas of basic research.

The topics within the various chapters cover (a) technical descriptions of the jet and space environments, (b) descriptions of current and potential vehicles and related equipment, (c) preventive medicine for these new environments, (d) personnel selection and training problems, (e) operator performance within the new vehicles, (f) medical monitoring and maintenance, (g) morale and motivational aspects, and (h) the causes and prevention of accidents. In general, the information appears to be current as of 1958. As might be expected with multiple authorship, there is considerable overlap and a lack of systematic order in the presentation of common and related topics. This forces the reader who is interested in any one particular topic to search each chapter rather thoroughly for all possible references to his problem. In addition, the order of the chapters would have been more logical if topic sequence as listed above had been followed, but this might be a matter of personal preference. The coverage of the chapters is also somewhat heterogeneous, with some being rather short and cursory overviews and others being quite lengthy and detailed including the presentation of basic information that is fundamental to human behavior in all types of

environment. In one or two rare instances, the authors expound at too great length in areas which do not appear to be their special competence.

This volume should certainly be of value to the several audiences for which it is intended. The need still exists, however, for a more systematic presentation of this material directly by authors rather than through the mediation of editors.

CHARLES W. HILL,
George Washington University,
Washington, D. C.

PSYCHOLOGY AND EDUCATION. By *Hirsch Lazarus Silverman*. Foreword by *James A. Brussel, M.D.* Introduction by *Benjamin Fine, Ph.D.* (New York: Philosophical Library, 1961, pp. 160. \$3.75.)

The volume is comprised of a series of selected essays, previously published by the author in various places. The author is Professor and Chairman, Department of Education and School Psychology, Graduate School of Education, Yeshiva University.

The essays range widely, as do the published writings of the author. In the volume under review there is discussed the psychology of democracy in education; discipline (psychological and educational aspects); delinquency; religion and psychology; religious education; existentialism; the exceptional child; and the interpersonal theory of Sullivan—together with an attempt to relate psychology and philosophy.

Each essay is thoughtful, and well addressed to matters of moment. The sum total cannot be reviewed, at least by the present reviewer. The cohesion lies only in systematic confusion (which probably includes us all) except that one feels the sincerity of the author himself.

Since the time when Educational Psychology was made definite and, therefore, simple in Thorndike, and during the post-Dewey interlude where it ceases to be a self-contained discipline, one turns to a volume such as this to see if Education and Psychology are really as closely related as we once thought; or whether education in Plato's sense can be translated so as to encompass all significant aspects of living, including psychopathology. This reviewer is glad to have seen the volume; but cannot find much comfort or inspiration therein.

W. LINE,
University of Toronto.

IN MEMORIAM

ERWIN STRANSKY, M.D.
1878-1962

Erwin Stransky, one of the great old men of the classical Vienna neuropsychiatric school, died in Vienna on January 28, 1962, in his 85th year. Born and raised in Austria, he graduated from the Vienna University as M.D. in 1900 and worked at the Vienna Neuropsychiatric University Hospital as a clinical assistant to Obersteiner and Wagner-Jauregg until 1909. In 1903 he became a lecturer in psychiatry and neurology on the ground of his thesis entitled "Contribution to the knowledge of certain acquired forms of dementia, also a contribution to the theory of dementia praecox," and in 1915 he became associate professor at the Vienna University. During World War I he served in the Austro-Hungarian Medical Corps. Following the annexation of Austria to Hitler's Germany in 1938 he was deprived of all his official connections and rights because of his partial "non-Aryan descent," and was able to survive the Nazi persecution physically unharmed thanks to his "Aryan" wife, an opera singer. Following the collapse of the Hitler regime and the reinstatement of the Austrian Republic in 1945, Stransky was able to resume his scientific and medical activities. Appointed physician-in-chief of the well-known neuropsychiatric hospital Rosenhügel, through his great personal efforts, he rebuilt it, practically with his own hands, from a war ruin to a flourishing centre for the treatment of neurological and psychiatric diseases. In 1946 the title of full professor was bestowed upon him, and in 1947 he became professor emeritus. During his medical career he became an active and honorary member of several scientific societies, among them the American Psychiatric Association which elected him to honorary membership in 1933.

Stransky was one of the last clinicians with a universal interest in the vast research area of psychiatry and neurology. His contributions were published in 295 papers and a large number of lectures over

6 decades. Very early he became interested in the problems of dementia praecox. Even before Eugen Bleuler he advocated a deeper psychological understanding of this illness. As early as 1903 he formulated the notion of "schism," anticipating Bleuler's concept of "splitting." Using a metaphor borrowed from clinical neurology, Stransky proposed the notion of "intrapsychic ataxia" as the basic psychopathologic element of dementia praecox. The lack of co-ordination between emotional processes ("thymopsyché") and thinking processes ("noo-psyché") described by Stransky is now generally accepted although often referred to as "incongruity of affect." Stransky emphasized the idea that in schizophrenia the feelings are not destroyed but rather separated from other mental phenomena. Even Kraepelin had to admit that Stransky's concept was "not without justification." Courageously and full of enthusiasm Stransky defended his theories against the theory of "amentia" during the first decade of this century, and against the currents connected with "deep" psychology, the attempts of psychogenetic interpretations of schizophrenia, as well as against the American formulations of schizophrenia in later decades. His summarizing study "From Dementia Praecox to Schizophrenia" published in 1954 is a fascinating analysis of the research in schizophrenia during five decades and, at the same time, of his own scientific development. As an excellent clinical psychiatrist Stransky made a large number of contributions to the phenomenology of other mental disorders, e.g., general paresis, epilepsy, Korsakoff's syndrome, and particularly manic-depressive illness. The chapter written by Stransky on the latter topic in Aschaffenburg's *Handbook of Psychiatry* has become a classic. Stransky was genuinely interested in questions concerning classification and nomenclature, as shown in his paper on the "Combined Psychoses," on paranoid conditions, on psychiatric and psychological methodol-

ogy, on the psychopathology of twilight states, *etc.* A large part of his time and endeavour was devoted to the theoretical and practical aspects of psychotherapy. In the twenties he wrote several papers on hysteria, "Critique of Psychoanalysis," "Direct Psychotherapy in Mental Diseases," "Viewpoints on the Theory of Neuroses," "Fashions and Short Circuits in Psychiatry," finally, in 1928, his basic study entitled "Subordination, Authority, Psychotherapy" in which he described his method of psychotherapy whereby the therapeutic effect was considered to be the result of the relationship between the patient's subordination to the therapist's authority.

Stransky was a staunch adversary of psychoanalysis. However, certainly Professor Hoff was right in his assumption that Stransky's attitude to psychoanalysis was highly ambivalent as shown by his early and inconspicuous use of notions coined by the psychoanalytic school of thought. Stransky stressed the importance of psychotherapy whose utilization by the general practitioner he strongly advocated. He was also an astute forensic psychiatrist whose description of the "initial criminal act" constituting one of the first symptoms in some cases of schizophrenia was but one in a large number of contributions to the specialty of forensic psychiatry.

As an experienced neurologist with deep interest in its basic sciences he made contributions to some problems of the peripheral nervous system during his early activities. Later on he studied specific phenomena in brain atrophy and other problems of cerebral pathology. His interest in the neuropathies, in the therapy with vaccines, and in the problem of non-specific therapy led him to the problem of therapy of multiple sclerosis. He devised a method of therapy with blood collected from elderly persons whom he considered as in a sense immunized against multiple sclerosis.

His interest in mental health, developed in his younger years, increased steadily, and led to the initiation of the Austrian mental health movement. His textbook, *Introduction to Mental Hygiene*, was one of the earliest treatises on that subject. From here he went on enlarging the realm of his considerations to problems of guidance of the

masses, of mental health activities in the interest of peace, and of *Psychopathy and Statesmanship* (1952), the latter study giving rise to some controversy. Finally he developed an enthusiastic interest in geriatric problems to which he was able to make important contributions.

Being a brilliant speaker Stransky was able to develop an extensive oratorical activity ranging from delivering papers at international and national scientific meetings to lectures in popular courses, evening classes, and senior high school classes. His audience, with which he easily established contact, was always fascinated both by his lectures and papers and by his vivid remarks and arguments in which he would invariably become involved as a discussant. He was quick witted, endowed with a sharp sense of humor, and an infallible memory which frequently helped him in fighting arguments, particularly concerning bibliographical references.

As one of his old time disciples may I add a few personal recollections. When I first met Professor Stransky in 1931 as a medical student eager to receive of the knowledge accumulated at the Vienna University over the centuries, I was deeply impressed by this elegant, handsome, extravert, enthusiastic teacher and leader of his audience. During the following terms I hardly ever missed one of his Saturday afternoon lectures during which he used to lead his small but devoted group of students into active participation in the examination and exploration of neurological and psychiatric patients and the discussion of questions regarding diagnosis, prognosis and therapy. He was a dedicated doctor who made no distinction between private and sick fund or clinic patients as far as his interest and devotion were concerned. When I last saw him in August of 1961 at the International Congress of Psychotherapy in Vienna he was still the enthusiastic orator, still young at heart, highly praised and respected by the younger generations of neuropsychiatrists under the leadership of Professor Hans Hoff. It was hard for me to believe when I learned of his death only five months later.

Milo Tyndel, M.D.,
Toronto, Canada.

PROCEEDINGS OF THE AMERICAN PSYCHIATRIC ASSOCIATION

SUMMARY OF MEETINGS OF COUNCIL AND EXECUTIVE COMMITTEE, MAY 1961 TO MAY 1962

This report presents in summary form the principal actions of the Council and the Executive Committee at meetings held throughout the year. Many routine matters, such as referrals to Committees prior to definitive action, are not included. Copies of the full minutes have been forwarded to the officers of each District Branch and Affiliate Society following the various meetings to keep their members informed of the matters that were considered and the action that resulted.

Executive Committee Meetings, June 16, Sept. 11 and Nov. 2, 1961. Established a Publications Review Committee to consider documents submitted via the Coordinating Committee Chairman or Council and to make specific recommendations to the Council regarding appropriate disposition of each document. The Committee was limited to 5 members appointed by the President for staggered 5-year terms. The Committee's expenses during the current fiscal year were to be charged against the Council Contingency Fund and the Budget Committee was instructed to set up an appropriate budget for the Committee effective Apr. 1, 1962. Was advised of the appointment of the following APA Representatives by the President: Dr. Howard V. Bair, Second International Medical Congress on Mental Retardation, Vienna, Austria, Aug. 1961; Dr. John A. P. Millet, Meeting of MEDICO, New York City, June 26, 1961; Dr. Herman C. B. Denber, French Congress of Psychiatry, Montpellier, France, June 1961; Drs. George S. Stevenson, John A. P. Millet, Robert H. Felix, D. Ewen Cameron and Aldwyn Stokes, Delegates, World Federation of Mental Health, Paris, France, Aug. 30 - Sept. 5, 1961; Dr. Donald W. Hastings, Women's International League for Peace and Freedom, Minnesota, June 26-30, 1961. Approved the purchase of 3,000 copies of the brochure, "Psychiatric Units in General Hospitals" by the Publications Revolving Fund. This brochure was prepared by the APA Committee in Liaison with the American Hospital Association and its counterpart committee from AHA. Agreed by consensus that where parallel committees exist in the parent organization and the District

Branches, appropriate data will be sent to the District Branches through the various liaison members of the APA Committees. Approved a standard \$3.00 registration fee for non-members at the annual meeting with the exception of foreign and distinguished guests, or interns and residents upon presentation of a letter of identification from their supervisors. These expected groups will be admitted without charge. Directed that those members scheduled to be dropped for non-payment of dues who send in full or part payment of their arrearage prior to the September Executive Committee Meeting should be retained on the membership rolls. Rescinded the action of Council which transferred a member to inactive status, restored him to active status at his request, and accepted payment of his dues. Reaffirmed its approval of the proposed Exploratory Conference on Mental Deficiency, approved the budget and financial arrangements recommended by the Committee on Mental Deficiency, and requested the President to appoint a Steering Committee in consultation with the Chairman of the Committee on Mental Deficiency. Authorized the Medical Director to continue to prepare the Agenda for the meetings of the Executive Committee and the Council, subject to the approval of the Secretary. Disapproved a recommendation that the category of Corresponding Member be eliminated from the proposed amendments to the Constitution and By-Laws. Also disapproved a recommendation that the category of Life Member be eliminated and voted to retain in the proposed amendments those Sections referring to Life Member (Article III, Sections 9 and 15; and Article IX, Section 3 of the Constitution. Chapter 2, Section 1c; Chapter 4, Section 1; and Chapter 6, Section 7 of the By-Laws). Disapproved by consensus the recommendation to define and enumerate "revocable" and "irrevocable" actions of the Executive Committee and the Council. Amended or revised several Sections of the proposed new Constitution and By-Laws after consideration of various recommendations of the Long Term Policies Commission and the Reference Committee. Approved the recommendation of the Internal

Management Commission that an Operating Reserve Fund should not be established at this time because of the availability of the Council Contingency Fund to meet unexpected expenses. Voted to retain Mr. Warren Magee as APA legal counsel for business purposes and in his absence to confer either with his associate or with the firm of Trammell, Rand and Nathan. Approved the following recommendation of the Internal Management Commission regarding Assembly communications as amended: "(A) *Intra-Assembly Communications*. A copy of all communications pertaining to District Branch affairs is to be sent to Central Office, addressed to the Medical Director, attention District Branch Office. The latter will ensure that copies of such correspondence are sent to the Recorder, the Speaker, and appropriate Officers of APA, for information and distribution as necessary. (B) *Other Communications*. Units of APA, including Officers, Committees, and Central Office will transmit copies of their District Branch correspondence to the Office of the Medical Director, attention District Branch Office, which will ensure that the Recorder, the Speaker and appropriate Officers of APA, receive copies for information and distribution as required." Approved the recommendation of the Commission that the responsibility for close surveillance of the financing, setting of rents, maintenance, costs, etc., of the APA real properties be delegated to the House Committee on a continuing basis, and that the Medical Director provide the Committee with the necessary data and support to accomplish this task. Approved the recommendation of the Internal Management Commission regarding the establishment of a Mail and Records Section in the Central Office and that all mail sent to the Central Office pertaining to Association affairs be addressed to the Medical Director. Rescheduled the 1964 annual meeting at the Biltmore Hotel in Los Angeles, Calif. to May 4-8. Authorized the President, at his discretion and after careful study of the situation, to make available from the Council Contingency Fund a sum not to exceed \$5,000 to assist the Joint Study on Continuing Medical Education. Directed the Secretary to express the interest of the APA in the general objectives of the MEDICO proposal that the Association set aside \$1.00 per member to support that organization financially and appoint a representative to serve on the MEDICO Board, but to indicate that it is not possible to levy an assessment on the membership for such a purpose. However, APA members will be encouraged to make voluntary contributions, and if this type of financial sup-

port is acceptable, the Executive Committee will consider the selection of an official representative to the Board. Approved the recommendation of the Ad Hoc Committee on Pre-Registration that the procedure as devised for the 1961 annual meeting be continued. Voted that there would be no revision of the present policy of rotation of Committee membership. Approved a change of name for the McGavin Selection Committee to the McGavin Selection Board. Approved the appropriation of an additional \$1,000 to the budget of the Committee on Constitution and By-Laws to permit the Committee to meet at the time of the Fall Committee Meetings. Approved a contract with the National Institute of Mental Health whereby APA will be paid the amount of \$4,025 to provide certain APA membership data to the Central Repository of Mental Health Manpower Information. Directed the Treasurer to inform those members whose dues are 3 years in arrears that they are being dropped from membership in the Association but to advise 3 individuals because of special circumstances that if and when their delinquent dues are remitted, they will be considered for reinstatement. Unanimously approved the action of the President in returning to the State of Maine its prepayment of charges for a Central Inspection Board report which has not been completed and commended him for his handling of the problem. Directed the Secretary to advise the Commissioner of the Department of Mental Hygiene of New York State that since the APA has not been able to complete the CIB report for Creedmoor State Hospital in a reasonable period, the \$2,000 fee paid to the APA will be refunded. The Secretary was also instructed to inform all hospitals involved for which a completion date has not been scheduled with reasonable certainty, that the CIB has been discontinued and its reports delayed indefinitely. The reports will be completed, if possible, but no charge will be made to the hospitals concerned.

Council Meeting, Nov. 24-26, 1961. Authorized a statement to President Kennedy at the request of the Committee on Public Health suggesting that if Federal budgetary reductions are necessary, they should be affected in programs other than in the health fields. At the direction of the President, Dr. Tompkins and Mr. Robinson drafted such a statement which was accepted by consensus. Approved by consensus the following statement: "The Public Health Committee considers the area of international tension and potential nuclear war to present both immediate mental health problems in their effect on the public, and potential

morbidity and mortality problems of staggering degree, and indicates that this area requires the attentive investigation by the National Institutes of Health." Ruled that the APA does not undertake to approve or disapprove individual prepayment plans for treatment. Agreed by consensus that the membership should be advised through the Mail Pouch that there are important limitations in their malpractice insurance coverage, such as those referring to the use of experimental drugs. Members should read their policies carefully, notify the insurance carrier promptly when they have difficulty, and seek legal advice when such is appropriate. Approved the recommendation of the Committee on Standards and Policies of Hospitals and Clinics, strongly reaffirming the policy that mental hospital administrators should be experienced psychiatrists with administrative ability. Directed the staff to develop a packet of material to provide information on this subject in further support of the policy of the APA regarding mental hospital administrators. Directed the Committee on Standards and Policies of Hospitals and Clinics to incorporate into their proposed restudy of mental hospital standards a re-examination of the role of the mental hospital administrator. Disapproved as premature a request from the Committee on Psychiatric Nursing for authority to sponsor a multidisciplinary conference and suggested that the proposal should be re-submitted for consideration together with specific supporting data. Deferred action on the request of the Committee in Liaison with the American Academy of General Practice for a change of name and directed the Committee to explore this matter with the Academy to determine their reaction. Authorized the Committee on Academic Education to solicit funds in the name of the Association to underwrite a conference on "The Role of the Psychiatrist in the Schools." Authorized the President to advise the Committee on International Relations that it may cooperate in the planning for the South American Congress of Psychiatry provided the APA is invited to do so. Commended the various Committees for their accomplishments in relation to the study of the report of the Joint Commission on Mental Illness and Health as well as in the other areas reported upon by the various Coordinating Committee Chairmen. Disapproved a proposal by the Nominating Committee to put 3 names in nomination for the officers of President-Elect, First Vice-President and Second Vice-President with members indicating their choice for each position by ranking the candidates by

number and the respective offices being awarded on the basis of totals. Directed that in the preparation of election ballots, the names of candidates for Councillor should be rotated so that each name appears on the list in a specific position an equal number of times. Considered the various provisions of the new Constitution and By-Laws proposed by the Committee on Constitution and By-Laws. Amended the Constitution by striking out the entire document and substituting the new provisions; amended the By-Laws by striking out all of them and replacing them with the proposed new By-Laws; and empowered the Executive Committee to act for the Council in reviewing and approving those Sections of Chapters 3, 4, 5, and 6 of the By-Laws that had not been acted upon at this meeting. Referred to the Executive Committee the proposed budget for the 1962-63 fiscal year. Authorized a Western Divisional Meeting in 1963 either in Los Angeles or San Francisco as determined by the appropriate local officials. Agreed by consensus that the Membership Committee should plan to hold two meetings during 1962. Commended the Moderator for the manner in which he handled a most difficult meeting.

Executive Committee Meetings, Jan. 15 and Mar. 5, 1962. Approved the proposed new Constitution and By-Laws as amended at this meeting and directed that they be transmitted as a finished document to the membership for information and consideration prior to a definitive vote by the membership. Directed that the proposed amendments to the Constitution and By-Laws should be submitted to the membership for consideration by mail ballot after being read at the 1962 annual meeting in accordance with the customary procedure. Directed that the Editor of the Journal be requested to publish in an early issue of the Journal, but not later than an issue which will reach the membership before the annual meeting, the revised text of the proposed amendments to the Constitution and By-Laws. In addition, the Association will purchase a sufficient number of reprints so that they can be distributed to the membership in attendance at the annual meeting and at the time of balloting. Directed that expenses related to the implementation of this action should be defrayed from otherwise unobligated funds of the Association. Revised and approved the official Position Statement of the Association regarding the final report of the Joint Commission on Mental Illness and Health entitled *Action for Mental Health*. Approved by consensus the preparation of a brief summary

statement to accompany the official Position Statement. Approved, as amended, the recommendations of the Internal Management Commission with regard to business practices in the Central Office as follows: 1. *Travel*. The travel budget shall be appropriated to the Office of the Medical Director where expenditures shall be made at the discretion of the Medical Director. Said expenditures to be within the budgetary limitations of each fiscal year, and in the best interest of the aims and objectives of the APA. 2. *Staff*. The maximum number of permanent positions on the staff and the amount of money to compensate for these positions shall be set by the Council each fiscal year. The Medical Director will operate within these conditions and within the established overall budget. 3. *Entertainment*. The entertainment budget shall be appropriated to the Office of the Medical Director who shall authorize expenditures at his discretion and within the budgetary limitations of the fiscal year. 4. *Overall Budget*. Subject to the limitations set forth in "2," above, the Medical Director shall have authority to transfer funds within the budget for operating purposes, provided that in no case will he transfer more than 25% of the official budgeted item without prior approval of the Treasurer. 5. *Miscellaneous Expenses*. Items in the budget falling within the categories of repairs, renovations, and furnishings shall be accounted for in the budget allotted to "Operation and Maintenance of the Central Office Building" or the appropriate budget item for other Association properties, rather than under "Miscellaneous." Appointed the President-Elect as an annual *ex-officio* member of the Reference Committee. Approved the recommendation of the Internal Management Commission that the Mental Hospital Service act as the secretariat for the American Association of Volunteer Services Coordinators. Approved the 1962-63 budget as recommended by the Budget Committee with the proviso that the Committee will be asked to review several specific requests for increased appropriations. Approved a supplemental appropriation of \$1400 for the Assembly budget during the 1961-62 fiscal year as a non-recurring item, and directed that funds should be transferred from the Coordinating Committee budgets to offset this appropriation. Approved pre-registration for the annual meeting as a policy of the Association as recommended by the Reference Committee. Approved the recommendation of the Reference Committee and directed that Council Meetings continue to be scheduled for two days except in unusual circumstances. Approved

the recommendation of the Publications Review Committee that no commitment be made at the present time to endorse or publish the proposed book, *Careers in Psychiatry*. Approved the guide lines prepared by the Publications Review Committee to implement its basic functions. Authorized the Ad Hoc Committee on Insurance to prepare a brochure on malpractice insurance at no expense to the Association. Authorized the President to appoint an Ad Hoc Committee to cooperate with representatives of the Japanese Society of Psychiatry and Neurology in the preparation of the scientific program for the joint meeting scheduled in Tokyo in May 1963. Restored to the membership rolls an individual previously dropped for non-payment of dues, accepted the arrearage, and directed that the individual's membership record be continued with no break in continuity. Voted to validate the mail ballot of Executive Committee members on two proposed amendments to the Constitution and approved the President's interpretation of the response. Agreed by consensus that there should be no adjustment of the approved budget for the 1962-63 fiscal year at this time. Authorized an increase of \$12,746.79 in the budget for the 1961-62 fiscal year for the following operations in the individual amounts specified by the Treasurer and directed that when necessary, these additional monies should be transferred from the General Fund: Mail Pouch, \$1,500; Medical Director's Office, \$4,000; Central Inspection Board, \$3,183.79; Elevator Modernization, \$963; Council and Executive Committee, \$500; Council Contingency Fund, \$600; Publications Office, \$2,000. Approved the transfer of funds in the amount of \$500 from the budget to the Coordinating Committee on Technical Aspects of Psychiatry to the budget of the Coordinating Committee on Community Aspects of Psychiatry as recommended by the Treasurer. Authorized the immediate termination of the Special Book Fund and the transfer of the cash balance of \$60.17 to the General Fund. Future undesignated cash gifts of a minor nature will be deposited in the General Fund. Directed that the Seymour D. Vestermarck Memorial Lecture Fund should be continued as a Restricted Fund with the present balance deposited in a separate savings account. Validated and made a matter of record its previous decision which was reached during a telephonic conference authorizing the APA General Counsel to develop a brief and to file it on behalf of the Association in the Jenkins Case. Directed that after the appellate court has reached a decision in the Jenkins Case, the appropriate details

should be distributed so as to reach the most people in the least expensive way. The Committee on Psychiatry and the Law will work with the staff in determining what information should be distributed, how it should be distributed, and who should write the necessary explanatory material. Directed the Chairman of the Coordinating Committee on Technical Aspects of Psychiatry to contact the Society for Adolescent Psychiatry to ascertain their willingness to consider a Round Table at the 1963 annual meeting as an adequate forum within the APA for their group, and to approach the Section on Child Psychiatry regarding the possibility of changing their name to include adolescence. Agreed by consensus that an appropriate letter should be sent to candidates for Fellowship following consideration of their applications by the Membership Committee and that the necessary letter should be prepared by the staff. Approved a resolution recommended by the Treasurer to establish a checking account in Toronto to pay local bills incurred during the 1962 annual meeting and directed that the account be limited to \$3,000. Approved the recommendation of the Committee on Psychiatry and the Law and ratified the President's personal statement on confidentiality as the official APA statement on the subject (statement prepared by Past-President Robert H. Felix). Established a Commission on Insurance to be comprised of 5 members appointed by the President and reporting directly to Council, which will be responsible for all insurance problems as they relate to the Association. The Commission's attention was directed to the desirability of maintaining a close liaison with the Committees on Private Practice, Mental Hospitals, and Liaison with the American Hospital Association. Approved the recommendation of the Committee on International Relations and authorized the appointment of an APA representative to the Advisory Board of MEDICO by the President. Approved the request of the AMA Council on Medical Education and Hospitals and directed that an appropriate panel of 5 names should be submitted annually for possible appointment to the Residency Review Committee. Approved the SK&F Foundation's proposal for the establishment of an APA President's Fund subject to the recommendation of the Committee on Grants and Awards. Approved the intent of the proposal to bind the Presidential Addresses beginning with President Barton with details to be worked out by the staff in cooperation with the Treasurer. Explorations will also be made into the possibility of securing funds to bind the addresses of Past-Presidents. Directed

that information copies of all official APA correspondence from Officers, Committee Chairmen, *etc.*, should be forwarded to the Central Office for incorporation into the permanent files. Approved a memorial to deceased members in the form of a book mounted on a lectern at the annual meeting and the subsequent mounting of the pages in a permanent volume at the Central Office. Directed that the U. S. Committee of the International Conference on Social Work should be advised that the APA cannot contribute toward the development of an exhibit for their 1962 conference because of budgetary limitations. Directed that the American National Council for Health should be advised that the APA cannot contribute toward the expenses of the 1962 International Conference on Health Education because of budgetary limitations. Appointed Drs. Henry Brill, Henry Brosin, and Henry Davidson as an Advisory Committee to the staff IBM Project. Were informed of the following Presidential appointments: Drs. Robert Daniels and William Sheeley as representatives to the Oct. 28, 1961 meeting of the Joint Study on Continuing Medical Education in Chicago; Dr. William Malamud as representative to the Anniversary Symposium of the Eastern Psychiatric Research Association in New York City on Oct. 27, 1961; Dr. Peter A. Martin as representative to the meeting of the American Occupational Therapy Association in Detroit on Nov. 6-8, 1961; Dr. John F. Briggs to the Committee on Relations with Psychology with term ending in 1963; Dr. Lewis Robbins to the Survey Board; Dr. Daniel Blain to the advisory committee for the implementation of the mental health manpower information and studies program of the Training Branch of the National Institute of Mental Health; Dr. Donald Hammersley as representative to the 1962 meeting of the National Association of Recreational Therapists; Dr. Johnathan Cole to the AMA Council on Drugs; Dr. T. Richard Gregory to serve as a one-man Ad Hoc Committee on the Biographical Directory; Drs. William Earley and William Sheeley as representatives to the meeting of the AMA Advisory Committee on Continuing Medical Education on Mar. 13, 1962; Drs. Francis O'Neill, John Blasko and Cecil Wittson as representatives to the Ad Hoc Citizens' Consultant Committee of NIMH to study training needs for mental hospital business administrators; Drs. Mathew Ross and Kenneth H. Gordon as representatives to the 66th annual meeting of the Academy of Political and Social Science in Philadelphia on Apr. 13-14, 1962; Dr. Eugene A. Hargroves as representative to the Regional

Conference on Aging sponsored by the AMA Committee on Aging, Charlotte, N. C., Apr. 13-14, 1962; Dr. Jack R. Ewalt as representative to the National Leadership Conference sponsored by the NAMH in Washington, D. C., Mar. 5-7, 1962; Drs. Walter Barton and Mathew Ross to attend the meeting at the AMA headquarters on Mar. 29, 1962 to hear the final report of the Joint Study on Continuing Medical Education; Ad Hoc Committee for Joint Meeting with Japanese Society of Psychiatry and Neurology in Tokyo, May 1963; Dr. Alfred Auerback, Chairman, and Drs. Karl Bowman, Robert Garber, Zigmond Lebensohn and Eric Wittkower; Dr. Jack R. Ewalt will serve as Honorary President and Dr. Henry Brosin as Honorary Vice-President in accordance with Japanese protocol. The President appointed those members currently serving on the Permanent Council of the World Psychiatric Association as a Committee to advise APA regarding its relationship with the WPA. These members are Drs. Daniel Blain, Francis Braceland, D. Ewen Cameron, Robert Felix and Winfred Overholser. Dr. Felix was appointed official representative to the 1962 meeting of WPA. Authorized the payment of dues to the WPA in the amount of \$20 for the years 1960 and 1961 and directed that this expense should be charged against the Council Contingency Fund. Referred a request for information from the AMA Committee on Medical Care to the Chairman of the Coordinating Committee on Community Aspects of Psychiatry for transmittal to an appropriate Committee in his group.

Council Meeting, May 5-6 and 10, 1962. Reduced the subsidy to the Journal from membership dues from \$4 to \$2 per member. Authorized the Assistant Medical Director to sign checks for a maximum of \$100 each on the petty cash account of the Central Office. Appointed the Assistant Medical Director as Budget Control Officer for the Central Office. Authorized the Treasurer to invest excess cash reserves in marketable securities with the counsel of the financial advisor. Designated the Treasurer as official representative of the Association to discuss with officials of the Modern Founders details regarding their fiscal policies and functions. Amended and approved the recommendations of the Committee on Membership regarding applicants for admission and changes of membership status and directed that the list be submitted to the membership for action. Commended Dr. Marvin Adland, Chairman of the Membership Committee, for his excellent and comprehensive report. Approved the recommendations of the Member-

ship Committee regarding transfer to Inactive status, remission of dues (as amended), and resignation in good standing. Accepted the list of members who are 2 years in arrears and will not receive the Journal, as an information item. Deferred action on the list of members who are 3 years in arrears until the Sept. 1962 meeting of the Executive Committee. Expressed its appreciation to Mrs. Frances Davis of the Central Office staff, who is about to complete 10 years of service with successive Membership Committees, in a Resolution submitted by the Secretary and approved by the Council. Commended Dr. Evelyn Ivey for her work as Chairman of the Board of Tellers. Approved two modifications of the proposed amendments to the Constitution and By-Laws. Amended the minutes for the Mar. 5, 1962 Executive Committee Meeting by deleting the last sentence of Item 9.4. Approved the establishment of the West Virginia Branch and the Onondaga (New York) District Branch upon recommendation of the Policy Committee. Empowered the President to appoint an Ad Hoc Committee to seek ways and means for advising on the implementation of the final report of the Joint Commission on Mental Illness and Health. Directed the Reference Committee to continue to study the subject of professional courtesy, taking into consideration all of its ramifications utilizing the APA Committee structure, and when the time is appropriate, to bring a recommendation to the Council for consideration. In the interim, the Council statement of May 6, 1954 (Item 38.2 of the minutes) will stand: "Council unanimously went on record as disapproving the making of charges by psychiatrists for single visits or for short term therapy in the case of physicians and their immediate dependents as defined by the AMA..." Accepted as official policy of the Association the report of the AMA's Committee to Study Relationships of Medicine with Allied Health Professions and Services (so-called McKeown Report, approved by the AMA House of Delegates) upon recommendation of the Reference Committee, and extended a vote of thanks to the Committee on Relations with Psychology for their work on this matter. Approved the recommendation of the House Committee to place in the Central Office photographs of President-Elect Branch and Incoming President-Elect Ewalt, together with President Barton, in the recent Presidents' collection as a measure of convenience, symmetry and economy. Approved the recommendation of the House Committee and reaffirmed its authority to purchase property 1807 R St. at a reasonable price not to exceed \$40,000 and

with "deliberate speed" at the discretion of the Committee. Approved the changes in qualifications for candidates for certification by the Committee on Certification of Mental Hospital Administrators upon recommendation by the Committee. Nominated Dr. Walter E. Barton as one of the 4 APA representatives on the American Board of Psychiatry and Neurology, Inc., for a term to expire in Dec. 1966. Was informed of the following Presidential appointments: Dr. William P. St. John as representative to the 1962 annual meeting of the Royal Medico-Psychological Association in London; Dr. Alvin Goldfarb as representative to the Conference on Aging, Ann Arbor, Mich., June 1962. Drs. M. Ralph Kaufman, Addison M. Duval, Elmer Caveny, Peter Regan and Herbert Gaskill as representatives to the AMA Residency Review Committee; members of the Commission on Insurance: Dr. Joseph Abramson, Chairman, and Drs. Charles K. Bush, John Cotton, Perry Talkington and Alexander Simon; Dr. Robert T. Morse and Mr. Robert L. Robinson to work with the Coordinating Committee of the American Association for the Advancement of Science for the Non-Commercial Educational Television Project; Dr. W. Horsley Gantt as APA representative on the Board of MEDICO. Approved the establishment of the West Hudson District Branch. Instructed the House Committee to engage an engineer's services for the purpose of conducting a survey of the Central Office. Elected Dr. C. H. Hardin Branch as Moderator. Elected Drs. Walter Barton and Daniel Blain to the Executive Committee. Approved the appointment of Drs. Edward Beaghtler and Rogers J. Smith to the Membership Committee. Approved the establishment of the following Ad Hoc Committees upon recommendation of the President-Elect: Joint Committee with Canadian Psychiatric Association; On Recognition of Psychiatric Service Personnel; Contract Survey Board; IBM Advisory Committee; On the Convocation; To work in Cooperation with the Japanese Society of Psychiatry and Neurology; Biographical Directory. Discharged the SK&F Foundation Awards Committee. Discharged the Committee on Committees since its work is being done by the Reference Committee. Approved in principle a proposed project between the Association's IBM Coding Project and the NIMH to improve the manpower information on psychiatrists in the U. S. and authorized the Central Office to prepare a contract with NIMH on the matter for consideration by the Executive Committee or the Council. Was informed of the following appointments by the President to the

Ad Hoc Committee to Study and Make Recommendations in the Implementation of the Report of the Joint Commission on Mental Illness and Health: Dr. Francis Gerty, Chairman, and Drs. Francis Braceland, M. Ralph Kaufman, Dana Farnsworth and Walter Barton. Authorized an Ad Hoc Committee to work with the AMA in planning and implementing the First Congress on Mental Illness, with appointments to be made at the discretion of the President and necessary funds to be allocated from the Council Contingency Fund. Authorized the Committee on History of Psychiatry to continue its oral history project. Authorized the Committee on Rehabilitation to seek funds from the Office of Vocational Rehabilitation and NIMH to hold a Workshop on Rehabilitation, with the proviso that they coordinate this action with the Committee on Grants and Awards. Discussed the use of experimental drugs in clinical research at the request of the Committee on Research and approved the following Resolution: "1. That the need to take action is urgent, 2. That the President of APA write to the President of AMA inquiring about the feasibility of a Joint Conference on the subject, 3. That this matter be referred to the Reference Committee with instructions that they proceed forthwith to mobilize appropriate APA Committees and establish appropriate liaison with other organizations in order to formulate a positive statement which may insure a continuation of research along these lines and at the same time provide protection for people who engage in such research, and 4. That the Reference Committee bring specific recommendations to the Executive Committee or Council as soon as practical." Approved a change of name of the Committee on Mental Deficiency to the "Committee on Mental Retardation." Approved the intent of the Committees on Psychiatric Nursing, in cooperation with the Committees on Social Work, Relations with Psychology, and Standards and Policies of Hospitals and Clinics, to meet with representatives from appropriate organizations at no expense to APA for an initial planning meeting on the possibility of multidisciplinary conference on patient care and to present periodic progress reports to the Executive Committee or the Council prior to subsequent action. Clarified a previous action by restating that a standard registration fee of \$3.00 will be charged for non-members at the annual meeting with the exception of foreign and distinguished guests or interns or residents and medical students upon presentation of proper identification. Approved the request of the Committees on Oc-

cupational Psychiatry and on Leisure Time and Its Uses to solicit funds for the purpose of producing their respective newsletters, that said money should be deposited in the APA treasury in a Restricted Fund, that the Treasurer should supervise the disbursement of this money, and that this action be cleared with the criteria established by the Committee on Grants and Awards. Dr. Branch announced the following appointments to the Ad Hoc Committee to Work with the AMA in Planning and Implementing the First Congress on Mental Illness: Dr. Lauren Smith, Chairman, and Drs. M. Ralph Kaufman, G. Wilse Robinson, Jr., and Robert Garber. Necessary expenses for this committee will be charged against the Council's Contingency Fund. Dr. Francis Gerty was appointed Chairman of the Committee on Long Term Policies. Approved honoraria in the amount of \$150.00, plus expenses, to both Professor Murray L. Barr and Professor John Money, guest speakers by invitation at the 1962 annual meeting. Agreed by consensus that the format of the annual meeting Opening Exercises should be changed to begin with official greetings, followed by the Presidential Address, after which all other re-

ports will be presented. Expressed sincere appreciation for the outstanding work of the Committee on Arrangements. Commended Dr. John Donnelly for his excellent work with the Program Committee during his 3 years as Chairman, not only for the very fine programs, but also for his good nature, tact and equanimity during his period of office. Continued the Commission on Long Term Policies for an additional 5 years. Authorized the office of Mr. Austin M. Davies to perform secretarial duties for the New York Society for Clinical Psychiatry; Mr. Davies to set an appropriate hourly fee for such services and bill the Society accordingly. Appropriated an additional \$2,000 to the budget of the Program Committee for the 1962-63 fiscal year.

As Secretary, I wish to express my great indebtedness to the officers and membership for their understanding and cooperation during the past year and to the staff of the Association for their ever-present and essential assistance in discharging the responsibilities of this office.

Harvey J. Tompkins, M.D.,
Secretary.

REPORT OF THE TREASURER

It is my pleasure and privilege as Treasurer to report that the financial condition of our Association is better at this time than for many years past.

This appears due to two principal factors. The primary one was the raise in membership dues effective April 1, 1961. The second was the improvement in internal management of the Association which has resulted from the work of the newly-formed Internal Management Commission. The good judgment of the Council and the various committees of the Association has been reflected in an efficiency of operations which has permitted us for the first time in several years to operate fully in the black.

You will remember that our recent financial difficulties of the past several years were caused by a shortage of cash reserves due to the outright purchase of our new Central Office Headquarters in Washington, D. C. In passing, I am proud to report to you that \$215,882 was pledged as gifts for the purchase of that new home and as of March 31, 1962, all but \$681 (about .3 of 1%) of that amount had been paid. This is a truly remarkable accomplishment and obviously reflects the deep affection and inter-

est of our members in Association affairs.

You will remember that we dug deeply into our reserves to finish out the year ending on March 31, 1961, rather than borrow membership dues from the next year's income which had been the custom for several years past. Thus, we were able to start the year 1961-62 with a clean slate and with the increased income which would come from the raise in dues. This was obviously a most favorable beginning.

In the previous year we had purchased two properties adjacent to our Central Headquarters building for \$57,570 on which we carry mortgages in the amount of \$30,515. Not allowing for depreciation of these properties, our income from rent during this year approximated the expense of operation.

We have for several years followed the standard practice of gradually setting aside money to cover depreciation costs on equipment, furniture, buildings and grounds of properties we own. Furniture and equipment have now been written down to the value of \$1.00 and we have this year for accounting purposes set up a Special Valuation reserve of \$50,000 which, if continued over the next 6 years,

would serve to reduce the valuation of our properties to a nominal value of one dollar. This policy represents a very conservative fiscal adjustment which will be most helpful financially as we try to work out our future space needs and possibly combine our office operations.

For the present operating year we had income to the General Fund of \$885,461 with expenses of \$858,583, or a net gain of \$26,878. The increase in membership dues produced an increased income of approximately \$110,000. With this increased income we are now on a firm financial operating basis.

In addition to the General Fund, we have in the Special Purpose Fund the sum of \$9,700, and in the Restricted Fund the sum of \$160,000. These funds cover the many grants, awards, special conferences and research projects operated by the Association.

We own marketable securities which have a present value of \$161,000 which cost us \$82,000. With our current improved cash reserves, additional investment in marketable securities is indicated and recommended and the Council has approved this recommendation.

With but a few exceptions caused by unpredictable and unforeseen situations, all of our Committees, Commissions and other units have lived within their budgets during the past year and to them I express our gratitude.

Several units in our Association have shown profitable financial gains during the year. I refer in particular to the Publications Section which showed a gain of \$12,000, the Newsletter and Mail Pouch a gain of \$15,000, and the Journal a gain of \$34,000.

To help support the operations of the Joint Information Service, we received from the National Association of Mental Health the sum of \$7,953, and for the Mental Hospital Service the sum of \$10,000. We are grateful for this assistance.

Careful attention will be given to the operation of the Mental Hospital Service in the Central Office unit because of a deficit in operations for the year of some \$15,000. This was primarily due to a reduction in projected income of \$12,000 in advertising and about \$6,000 in subscriptions.

At the request of the Internal Management Commission, the Treasurer spent additional time during the year supervising the detailed fiscal operations of the Association. It is believed this has been of some benefit. Certain weaknesses in operations were uncovered and corrected. Certain new methods have been recommended including the establishment of a budget control officer in the Central Office of the Association.

In conclusion, I would like again to assure the membership that the funds of the Association are received and disbursed under proper operating procedures and are safeguarded at all times.

My special thanks are extended to Mr. Austin Davies, Dr. Bart Hogan, and Mr. Joseph Turgeon for their unflagging devotion to the fiscal affairs of the Association and for their outstanding cooperation with the Treasurer during the year.

Addison M. Duval, M.D.,
Treasurer.

REPORT OF COORDINATING CHAIRMAN : COMMITTEES ON TECHNICAL ASPECTS OF PSYCHIATRY

Conducting the affairs of the American Psychiatric Association can be a very confusing as well as an exciting job. If it is well done, as many members as possible should participate in determining its policies as well as in carrying them out. A neat balance between seeming authoritarianism and utter chaos should somehow be achieved. It is the job of a coordinating committee chairman to interpret the actions of the Officers and the Council to the Committees and through them to the District Branches and the general membership. Likewise it is his duty to communicate the wishes and sentiments of the members, speaking through their Committees, to the senior gov-

erning body. Psychiatry is oversold and under-supported. By such examinations as those which have been conducted this year by all the Committees on the report of the Joint Commission on Mental Illness and Health, it should be possible to aid in giving the public realistic information of what can be expected from psychiatry and related fields and at the same time acquainting the public, and particularly its legislative bodies, with the scope of effort required to solve the major mental health problems. Thus we should not have to continue forever in the vulnerable position of always having to deal with problems whose solutions are beyond our resources.

Groups with special interests have a particular responsibility to see that those whom they represent are not neglected. Thus the Committee on Aging, under Dr. Maurice E. Linden, has been engaged through research in preparing a statement regarding the place of geriatric education in medical schools and in psychiatric residency programs. They have developed a policy statement for the APA on the King-Anderson bill, not with regard to whether the bill itself is desirable or undesirable, but attempting to see that this or any other bill take into consideration the needs and dignity of elderly people. The Committee held a Round Table at the meeting and chaired a section program.

The Committee on Childhood and Adolescence, Dr. Reginald S. Lourie, Chairman, has been quite active in standard setting and position determining functions, some of them in collaboration with other organizations with similar interests and goals. Among these are 1) the Joint Conference on Training in Child Psychiatry to be held with the American Academy of Child Psychiatry in January 1963, 2) the Task Force on Juvenile Delinquency aided by a grant from the American Child Guidance Foundation, 3) the National Association of Juvenile Court Judges with whom liaison work has been initiated. Work on preparing a list of consultants in child psychiatry for South American countries has been under way for the WHO. The Committee has also reviewed a bibliography for trainees in child psychiatry prepared by Dr. I. N. Berlin and has recommended to the Council that it be published by the APA.

The Committee on the History of Psychiatry, under the guidance of Dr. J. Sanbourne Bockoven, has concentrated its work this year on two areas. The first is the stimulation of research and study which draws its data from sources already safely preserved in libraries, public or private. The second is the rescue of other valuable sources of historical knowledge before they are forever lost. Among the latter are the memoirs of many of our present older colleagues, men and women who have shaped the course of modern psychiatry in America. These the Committee hopes to preserve by a series of tape-recorded interviews, now underway. There are also many records and documents in various mental hospitals throughout the United States and Canada which are of considerable historical significance but which are in danger of being discarded as building programs develop. In the private libraries of many of our members are valuable and even unique items that ought ultimately to be

housed in our central collection.

The Committee on Medical Education, with Dr. C. Knight Aldrich in charge, has been quite active in preparation for the forthcoming conference on Graduate Psychiatric Education.

Many hospitals are requesting psychiatric teaching of their interns and residents. In view of the fact that a considerable number of internships and residencies in other specialties are located in institutions without psychiatric training centers, the active collaboration of all members of the District Branches is desirable, whether or not they are affiliated with psychiatric training centers. It is essential that psychiatrists assist in developing teaching plans and mobilizing psychiatric resources in their own communities to meet these emerging demands.

The Committee on Mental Deficiency, led by Dr. George Tarjan, has picked up some powerful support from a variety of sources during the past year, and its plea that mental retardation should be viewed as a part of the total mental health problem has been widely heard even though not yet as fully heeded as it would like. Nevertheless, the growing public and professional awareness of the extent and nature of mental retardation, and especially the appointment of the President's Panel on the subject, has greatly encouraged the Committee.

Much of the Committee's activity during the year was devoted to the preparation and conducting of an Exploratory Conference on Mental Retardation. This was held at the new University of Kentucky Medical Center with 30 persons in attendance, representing 15 organizations. Financial aid was received from the Project on Technical Planning in Mental Retardation of the American Association on Mental Deficiency.

The participants recognized the increasing magnitude of the problem of retardation. It was thought that the solution will involve medicine and its various specialties, and a number of other professional disciplines. Inter-specialties communication and interest in mental retardation require changes in the training of medical students and in the preparation of specialists. Inter-disciplinary approaches to such a complex phenomenon as retardation should be emphasized.

The Committee on Public Health, Dr. Benjamin A. Pasamanick, Chairman, has been concerned with improving relations between District Branches and local mental health societies. Relatively inactive local societies tend to inhibit each other, and this is to be deplored. In general, the Committee sees so many things that should be done in promoting psychiatric

aspects of public health that it is almost literally overwhelmed by the magnitude of the tasks that need to be done in this field.

The Committee on Rehabilitation, under the leadership of Dr. George W. Brooks, is focusing on the role of psychiatrists in rehabilitation programs and activities of all kinds. It is concerned with such questions as, When and under what circumstances should the psychiatrist be captain of the team and when should he more properly serve as consultant? What defects in psychiatric education make proper functioning of a psychiatrist in rehabilitation programs difficult? As with many other committees, the relations of psychiatrists to members of other disciplines is a constant preoccupation.

The Committee on Research, guided by Dr. Milton Greenblatt, always very active in the planning and holding of regional research conferences, sponsored two of them this year, one at Yale University on "The EEG Correlates of Behavior," the other at the University of Southern California on "The Acute Psychosis." One report of a previous conference has been published and another is in press. McGill, Queen's and Duke Universities are now in the

midst of preparation for research conferences. A feature of this Committee's activities is the annual participation in the program of the American Association for the Advancement of Science. This year a symposium on "Genetics and Evolution in Relation to Human Behavior" was held in collaboration with the American Anthropological Association. Dr. Tigani el Mahi of WHO was selected to give the Adolf Meyer Lecture.

The Committee on Therapy, with Dr. Henrietta R. Klein as leader, has made a survey of attitudes toward the use of group psychotherapy, particularly where there are inadequate training facilities for interesting desirable personnel for the task. The survey points up the uneven training of many who use this technique, and the inadequate training facilities for those who wish to become proficient in it.

Of necessity this report barely suggests the large amount of work done by Committee members. To all of them should go our warmest thanks.

Dana L. Farnsworth, M.D.,
Coordinating Chairman.

REPORT OF COORDINATING CHAIRMAN: COMMITTEES ON COMMUNITY ASPECTS OF PSYCHIATRY

All the Committees of the APA this year made special studies of the Report of the Joint Commission on Mental Illness and Health in relation to their areas of concern and forwarded their conclusions to Council for consideration in the preparation of the APA statement on *Action for Mental Health*. The Committees also reviewed their terms of reference or an outline of their functions to contribute to the formulation of a Manual or Handbook on Committee and other Association operations prepared by the APA staff to be in pilot use for one year before final adoption.

The Committee on Academic Education, of which Dr. Dan Funkenstein is Chairman, has received approval of Council to organize a Conference between School Administrators and Psychiatrists to enhance a realistic attitude of each to the other. This group is concerned that psychiatrists do not generally appreciate the opportunities they have in improving mental health through work with the schools. Special attention is being given to the inclusion of school mental health work in residency training programs. The Committee has worked

with the Committee on Preventive Psychiatry on this matter.

The Committee on Disaster and Civil Defense, with Dr. Ed Kollar as Chairman, has had active and productive discussion with personnel of the Office of Civil Defense, culminating in a Report on the Utilization of Mental Health in the Event of Disaster. This, in turn, was made a part of the program of the Mental Hospital Institute, so that the findings could get immediate attention. The group is now turning to the more local problems of what the functions of practicing psychiatrists should be in disaster situations and how they should be incorporated in the medical planning of the area. They are also concerned with the problems of the education of the public regarding the hazards of thermonuclear disasters. As have many other committees, this group has given particular attention to working with the Committees of the District Branches.

The Committee on International Relations is of increasing importance in the APA and, with Dr. Jack Millet as Chairman, has had a number of thorny problems referred to it. In

addition, it has developed excellent program material for the annual meeting. The Round Tables, listed in the program, proved of great interest. Among the Scientific Exhibits was one concerning their subject.

The Committee on Leisure Time and its Uses, Dr. Paul Haun, Chairman, carefully sees to it that its members eliminate this problem by working very hard. Its *Newsletter* is helpful in keeping abreast of the field, and the orientation packet they sent contained background material of current information about this area. It planned an open meeting of the Committee for the annual meeting so that APA members could see how it goes about its work. It has formulated plans for bringing other professional organizations, both medical and lay, together to make better progress in meeting the problems incident upon shortened working hours and other issues. Publications are being prepared on various aspects of the problem, among others, that of leisure time in retirement.

National Defense, with Dr. John Caldwell as Chairman, meets with representatives of the Military Services to maintain relationships between our Association and the Military and to strengthen the psychiatric services of our armed forces during peace time. In addition, the group has been concerned with the issue of psychiatric standards for civil airmen.

The Committee on Occupational Psychiatry, of which Dr. Ralph Collins is Chairman, and to which he has furnished leadership for a long time, has had the pleasure of seeing the word "physical" eliminated from the title of the official governmental body, The President's Committee for the Employment of the Physically Handicapped, concerned with rehabilitation and employment of all the handicapped. This change is more than mere verbiage; it is a symbol of a broadened outlook which has been cultivated assiduously by your Committee for years. This group distributes a *Newsletter* concerning the field of psychiatry in industry. It has helped in the organization of conferences on mental health in industry. It composes the annual review on Occupational Psychiatry for our Journal. Its brochure, *Troubled People on the Job*, has sold 28,000 copies and returned a substantial profit to the APA. It is planning a companion piece designed for personnel directors.

The Committee on Preventive Psychiatry, with Dr. Henry Work as Chairman, is in the process of publishing a series of three papers for general practitioners on psychiatric alarm signals. As already noted, it has collaborated with the Committee on Academic Education and is now concerning itself particularly with

mental health opportunities in the elementary schools.

The Committee on Religion and Psychiatry, Dr. Earl Loomis, Chairman, has been reviewing the training of chaplains for service in mental hospitals and presented a Round Table discussion at the meeting. The subject was "The Significance of Religious Attitudes in Psychiatric Patients."

Dr. Seymour Rosenberg is the Chairman of the Committee on Veterans. It has been concerned with the maintenance of standards in this service and has worked with its leaders toward the end. It has proposed greater community involvement of the VA Hospitals and Clinics. In addition, it is studying the relationships between Medical Education and the VA with a view to maintaining and strengthening their relationships.

The last Committee of this group is that on Public Information of which Dr. Bob Morse is Chairman. No group in our Association except the Council and Executive Committee appears to me to carry the continuous load of consultation, publication, review and reference that this group does. The Glossary continues to sell in enormous numbers. It has been concerned with the best ways to offset the effects of Maisel's destructive article in the *Reader's Digest*, as noted in the *Newsletter*. It has arranged the facilities for the press here and encourages you to collaborate in the open press policy of the Association which this Committee originated and which has proved so successful.

Working with District Branch Committees has been mentioned in several of these reports. It is very easy to get into the frame of mind that says, "If they don't contact me, why should I contact them?" Particularly when one has an idea that seems worthy of study by a Committee at the level of the whole Association. May I plead with the Membership and particularly with Committees of the District Branches not to hesitate to contact your APA Committees, to feed them ideas, to offer to help them in collecting information or in formulating policy to be acted upon by Council. Committee cooperation and information-giving is not a one-way street. Two-way traffic will carry more stimulation to both local Committees and those of the Association as a whole.

Finally, I want to thank the members of the Committees, and particularly the Chairmen, for the excellent way in which they have met deadlines and accepted responsibilities throughout the year.

Paul V. Lemkau, M.D.,
Coordinating Chairman.

REPORT OF COORDINATING CHAIRMAN : COMMITTEES ON PROFESSIONAL STANDARDS

It should be clearly evident to anyone who has followed the trends in this Association that, in recent years particularly, there has been a progressively increasing activity on the part of its Committees. It should also be evident that the continuing responsibility with which the Committees are charged require attention throughout the year. It follows then that the two fixed occasions for the formal meetings of the Committees in the fall and at our annual meeting are merely highlights in an on-going process.

This statement is in the way of a preface to a formal report on the concerns and activities of your Committees. It should be obvious that the time permitted for their reports at the meeting barely allows a summary of the highlights of their work in progress. What follows, therefore, in a quantitative sense does scant justice to their zeal and the importance of the several areas to which they address their attention.

Inasmuch as the Association was a signatory to the creation of the Joint Commission on Mental Illness and Health, its report was a matter of paramount interest to all the Committees. Accordingly each of the Committees concerned with Professional Standards, in response to the charge of the President reviewed in detail the summary contained in *Action for Mental Health* and especially those subdivisions of it which properly are the purview of the Committee's function. Their individual thoughtful and detailed considerations were collated at the time of the fall 1961 meeting and subsequently reported to the Council at its November 1961 meeting. This leaven contributed to the Council's subsequent deliberations and action on the Report of the Joint Commission.

The Committee on Psychiatry and the Law : Under the able chairmanship of Dr. Kenneth G. Gray, the Committee, both collectively and through the enterprise of its individual members as liaison agents, has continued to relate its activities to the entire field of forensic psychiatry in both its civil and criminal aspects including the correctional field. In this regard, it is occupied with the compilation of information about diminished responsibility, tests of criminal responsibility in various jurisdictions and the formulation of data recommending desirable positions for the Association on such important matters as granting privilege to the communication between psychiatrists

and their patients and the question of psychologists acting as expert witnesses in criminal trials.

The tasks under the aegis of this Committee are for the most part long range. They require not only deliberative judgment of a high technical order but also a quality of generality which will make them useful to the many jurisdictions in which they have to be applied specifically.

Psychiatry and Social Work : Capably chaired by Dr. Ner Littner, this Committee necessarily is involved in an extensive network of liaison relationships with other Committees of this Association at the national level, 22 regional committees in the District Branches and the more important national co-professional organizations and councils. Stemming from this cooperative effort are plans and action on such matters as national and regional workshops, the establishment of mutually acceptable standards, the sponsorship of technical papers—in short the facilitated interchange which will insure the continuing harmonious relationships with this sister discipline.

Committee on Psychiatric Nursing : Dr. William Hall has given sage guidance to the extending work of this Committee. The problems posed by the broad areas of psychiatric nursing, as you know, ramify far beyond the professionally registered nurse to include concern for the recruitment, training and the standards of psychiatric aides and technicians. Numerically, these workers en masse constitute the largest single group of personnel who have direct and continuing contact with the psychiatric patient in the hospitals throughout the country. Accordingly, this Committee has been particularly interested and especially active in cultivating affiliations with nursing groups and associations on both national and local levels. This is reflected in its efforts to formulate plans for a Multidisciplinary Conference as well as its joint effort with the National League for Nursing in the publication *An Approach to Education of Psychiatric Nursing Personnel*.

Committee on Liaison with the Academy of General Practice : Under the able direction of Dr. Philip Solomon, the Committee has been engaged extensively in the co-sponsorship of teachers' colloquia, joint meetings with companion representatives of non-psychiatrist physicians groups, round table discussions and in efforts to implement more effective communication with affiliate Committees among the

District Branches. All of this work is directed to the end of collaboration with practicing physicians interested in the use of psychiatric techniques.

The Committee on Standards and Policies of Hospitals and Clinics : This Committee, under the skillful chairmanship of Dr. S. T. Ginsberg, is conducting an extensive study of standards and policies which encompass the entire range of private and public hospitals, clinics and services. This will eventuate in a revision of the Associations published Standards which was last revised in June 1958. Coupled with this enormous task the Committee is also inquiring into the criterion issues which lay behind these matters.

The Committee on Private Practice : Under the effective chairmanship of Dr. Joseph S. Skobba, the Committee has formulated recommendations to Council suggesting a modification of the traditional American Psychiatric Association—American Medical Association policy position with regard to the matter of fees for services to physicians and members of their families. Then too, the thorny matter of adequate and equitable insurance coverage for psychiatrists and their patients is of continuing concern to this Committee which represents the Association's interests vis-à-vis insurance carriers.

Committee on Relations with Psychology : This Committee with the skillful direction of its chairman Dr. Joel S. Handler continues to strive to establish and maintain amicable relations with clinical psychology through the agency of working jointly for a shared responsibility which will protect the interests of the patient, provide for mutually agreeable educational standards, effect a collaborative approach for the resolution of negotiable differences and the attainment of common goals at the District Branch as well as the national level. In concert with the American Medical Association it continues to seek a uniform and standardized basis for cooperation with all allied disciplines concerned with diagnosis and treatment of patients for whom physicians have a primary responsibility.

Committee on Nomenclature and Statistics : Under the able direction of its chairman, Dr. Henry Brill, this Committee has continued to address itself to the knotty problems inherent in the formulation of a uniform statistical classification of mental disorders. Their en-

deavors have required participation in both national and international conferences which have the hopeful expectation of producing a standardized system of notation adequate to the needs of the profession.

Committee on Liaison with American Hospital Association : Ably chaired by Dr. Raymond W. Waggoner, this Committee in its joint meetings with companion members of the American Hospital Association has expressed its feelings that nationwide studies into early, less expensive and more human forms of community care be made by the federal government. Similarly it is preoccupied with the very important matter of Blue Cross and other prepayment coverage for mentally ill patients. Related to this it sees within its purview matters relating to payment for care of medically indigent psychiatric patients in general hospitals.

Committee on Mental Hospitals : This Committee whose effective chairman is Dr. Lauren Smith has among its many interests and responsibilities matters relating to the Mental Hospital Institute. While the Committee feels that the participation of non-medical staff personnel is important it stresses the role of the Institute as a forum for the medical staffs of these hospitals. Since the Report of the Joint Commission is especially concerned with the core problem of the mentally ill in hospitals, its programmatic recommendations have been the focus of detailed analysis and critical review by this Committee. These have been made available to the Council.

The Ad Hoc Committee on Recognition for Psychiatric Service Personnel : Aided by the adroit chairmanship of Dr. Philip Reed, this Committee has not only formulated general plans of operation for the synthesis of the many disparate groups involved in the care and treatment of the mentally ill but also has launched pilot Mental Hospital Workshops in several states which hold the promise of workable models for future enterprises designed to solidify the morale of workers in these areas.

As Coordinating Chairman of these Committees on Professional Standards, I commend the expanded version of these reports which are on file in the Central Office, to your individual and collective attention, for they intimately concern the prime purpose of this Association.

Howard P. Rome, M.D.,
Coordinating Chairman.

FELLOWSHIP LECTURE
THE IMAGINATIVE AND THE IMAGINARY¹

NORTHROP FRYE, LL.D.²

I should like to begin by distinguishing two social contexts of the human mind. What I say in this connexion will be familiar enough to you, but I need to establish some common ground between an association of psychiatrists and a literary critic. Man lives in an environment that we call nature, and he also lives in a society or home, a human world that he is trying to build out of nature. There is the world he sees and the world he constructs, the world he lives in and the world he wants to live in. In relation to the world he sees, or the environment, the essential attitude of his mind is that of recognition, the ability to see things as they are, the clear understanding of what is, as distinct from what we should like it to be. This is an attitude often associated, sometimes correctly, with the reason. I should prefer to call it "sense," because it is a pragmatic and practical habit of mind, not theoretical, as reason is, and because it requires emotional as well as intellectual balance. It is the attitude with which the scientist initially faces nature, determined to see first of all what is there without allowing any other of his mental interests to cook the evidence. And it is, I should think, the attitude that psychiatry would take as the standard of the "normal," the condition of mental health from which mental illness deviates.

The other attitude is usually described as "creative," a somewhat hazy metaphor of religious origin, or as imaginative. This is the vision, not of what is, but of what otherwise might be done with a given situation. Along with the given world, there is or may be present an invisible model of something non-existent but possible and desirable. Imagination exists in all areas of

human activity, but in three of particular importance, the arts, love and religion. Where we see a landscape, a painter also sees the possibility of a picture. He sees more than we see, and the picture itself is the proof that he really does see it. The standard of reality does not inhere in what is there, but in an unreal and subjective excess over what is there which then comes into being with its own kind of reality. In love, we frequently hear the voice of sense in some such phrase as "I don't know what he sees in her," or vice versa. But it is generally admitted that here it is the subjective excess over reality which is appropriate. Similarly in religion. The New Testament defines faith as the evidence of things unseen: reality in religion is not "there": it is brought into being through a certain kind of experience. The religious life is, like the artist's picture, the manifestation of such experience in the world of sense, or what the gospel calls letting one's light shine.

The imaginative or creative force in the mind is what has produced everything that we call culture and civilization. It is the power of transforming a sub-human physical world into a world with a human shape and meaning, a world not of rocks and trees but of cities and gardens, not an environment but a home. The drive behind it we may call desire, a desire which has nothing to do with the biological needs and wants of psychological theory, but is rather the impulse toward what Aristotle calls *telos*, realizing the form that one potentially has. As desire, it works dialectically, separating what is wanted from what is not wanted. Planting a garden develops the conception "weed," a conception of vegetable value unintelligible except in the context of a garden.

The attitude we have just called sense can only distinguish itself from what is below itself. It can separate the real from the

¹ Read at the 118th annual meeting of The American Psychiatric Association, Toronto, Canada, May 7-11, 1962.

² Principal, Victoria College, University of Toronto, Canada.

imaginary, sense from nonsense, what is there from what is not there, but it has no criteria for recognizing what is above itself. It is a fact of experience that the world we live in is a world largely created by the human imagination. It is a part of sense's own recognition of reality that there must be a standard above sense, and one that has the power of veto over it. But it is the resemblance between vision and hallucination, ecstasy and neurosis, the imaginative and the imaginary, that impresses itself on sense. These resemblances are, of course, obvious and remarkable. The creative and the neurotic reactions to experience are both dissatisfied with what they see; they both believe that something else should be "there"; they both attempt to remake the world of experience into something more responsive to their desire. There are equally important differences, but in themselves the visions of the artist, the lover and the saint can only be regarded by sense as illusions, and all that sense can say about them is that certain significant types of activity seem to be guided by illusion.

We may therefore see the creative imagination as polarized by two opposite and complementary forces. One is sense itself, which tells us what kind of reality the imagination must found itself on, what is possible for it, and what must remain on the level of wish or fantasy. The other pole I shall call vision, the pure uninhibited wish or desire to extend human power or perception (directly or by proxy in gods or angels) without regard to its possible realization. This polarizing of creative power between vision and sense is the basis of the distinction between the arts and the sciences. The sciences begin with sense, and work toward a mental construct founded on it. The arts begin with vision, and work toward a complementary mental construct founded on it. As sense is incorporated in science, and as science continually evolves and improves, what sense declares to be impossible in one age, such as aeroplanes, may become possible in the next. The arts do not evolve or improve, partly because vision, being pure wish, can reach its conceivable limits at once. The aeroplane is a recent invention, but the vision that produced it was already ancient

in the arts when Daedalus flew out of the labyrinth and Jehovah rode the sky on the wings of a seraph.

But there may be considerable differences of emphasis within the arts themselves. Some cultures have a more uninhibited vision than other cultures: we find the most soaring imaginations, as a rule, in defeated or oppressed nations, like the Hebrews and the Celts. The attitude in the arts that we call "romantic," too, tends to stress vision rather than sense, and our ordinary use of the word indicates that a "romantic" approach to things may sometimes be in danger of a facile or rose-coloured idealization. On the other hand, a culture may be dominated by a feeling of proportion and limitation derived ultimately from what we have been calling sense, and a culture of this kind may achieve the clarity and simplicity that we associate with the word "classical." The most impressive example of such a culture is probably the Chinese, but in our Western tradition we tend naturally to think of the Greeks.

Greek culture was founded on the conception of *dike*, a contract entered into by gods, man and nature, where each accepted certain limitations. The working out of this contract was the process of *ananke* or *moira*, words that we translate, very loosely, as "fate." Zeus, in the *Iliad*, goes to bed with his consort Hera and nearly allows the Greeks to win the Trojan war, that being Hera's idea in getting him to bed, and scrambles out in time to help the Trojans, whom on the whole he prefers. But the contract says that the Greeks are to win in the end, and Zeus himself dares not ignore it. And if the contract binds even the king of gods and men, still more is man bound to avoid the proud and boastful spirit that the Greeks called *hybris* and saw as the main cause of tragedy; still more must he avoid excess and seek moderation and limits in all things. Know thyself, said the Delphic oracle, implying that self-knowledge was the final secret of wisdom. For man's mind is turned outward to nature, and his knowledge of himself is an inference from his knowledge of the much greater thing that is not himself.

The classical inheritance was incorporated into later Western culture: medieval

philosophers described the attitude we call sense as *prudential*, and gave it a central place in their moral hierarchy. Even so, the attitude of the age of Shakespeare to sense and imagination was very different from ours, and perhaps we can learn something about our own age by examining the differences.

When Shakespeare's Theseus, in *A Midsummer Night's Dream*, classified "The lunatic, the lover, and the poet," as being "of imagination all compact," he was expressing an Elizabethan commonplace, and one usually summed up in the word "melancholy." Melancholy was a physiological disturbance caused by the excess of one of the four humours, but this excess in its turn was the cause of emotional and mental illness. Body and mind were therefore treated as a unit: a collection of remarkably cheerful songs bears the title "Pills to Purge Melancholy." There were two kinds of melancholy. One was a disease; the other was a mood which was the prerequisite of certain important experiences in religion, love or poetry. Love and poetry were combined in the literary convention within which the bulk of poetry in that age was produced. A young man sees his destined mistress and instantly falls a prey to melancholy. He stays awake all night and keeps his house dark all day; he mopes, sighs, forsakes his friends, turns absent-minded and slovenly in his appearance. More to the point, he writes poetry incessantly, complaining of his lady's inflexibility, cruelty and disdain. It was understood that a poet could hardly get properly started as a poet without falling in love in this way, and that a lover was hardly doing his duty by his lady without leaving a stack of lyrical complaints at her door. In the background was the religious experience on which this conventional love was modelled, and of which it was to some extent a parody: the experience of becoming aware of sin and the wrath of God, of the necessity for supplicating grace and acceptance.

Melancholy of this kind was certainly an emotional disturbance: it could become a mental disease, or at least there are many love poems threatening madness or suicide to impress an obdurate mistress. Normally, however, such disturbance was more in the

nature of a calculated risk, undertaken for the sake of a certain intensity of experience. It was a kind of male pregnancy, a creative state with some analogies to illness. But melancholy as a disease was equally familiar, and Shakespeare's audience would have recognized its characteristic symptoms in Hamlet. The indecision, the inability to act through "thinking too precisely on th' event," the clairvoyant sense of the evil and corruption of human nature, the addiction to black clothes, the obsession with death both in others and in oneself, the deranged behavior that could easily modulate into actual madness with little outward change, were stock attributes of melancholy. So too was the fact that Hamlet, though not a poet, as he tells Ophelia, shows many similarities to the poetic temperament. Polonius, who has literary tastes, has a literary explanation for Hamlet's melancholy: he is in love with Ophelia; but the audience has already been given a more convincing reason. Of course a tendency to melancholy would be greatly increased if one had been born under either of the two melancholy planets, Saturn and the moon, which tended to make one saturnine or lunatic. Nations as well as individuals had their tutelary planets, and the fact that England's was the moon was responsible for many jokes, including some from Hamlet's grave-digger.

Not only the most fascinating play of the period, but its greatest prose work (in England), has melancholy for its theme. Burton's *Anatomy of Melancholy* is an exhaustive analysis of the causes, symptoms, treatment and cure of melancholy, with two enormous appendices on love melancholy and religious melancholy. Burton was an Oxford don, and his chief amusement is said to have been going down to the Isis river and listening to the bargemen swear. The story may be true, or it may have been invented by someone who noticed that the qualities of Burton's prose, with its vast catalogues, piled-up epithets, Latin tags, allusiveness and exhaustive knowledge of theology and personal hygiene, are essentially the qualities of good swearing. Burton assumes rather than discusses the connexion of melancholy with creative power: being a scholar himself, like Hamlet, he associates it rather with the scholarly temperament,

and includes a long digression on the miseries of scholars. On religious melancholy his position is simple: one can best avoid it by sticking to the reasonable middle way of the Church of England, avoiding the neurotic extremes of papist and puritan on either side. But in love there is no reasonable ground to take, for its very essence is illusion. On this point we had better let Burton speak for himself:

Every lover admires his mistress, though she be very deformed of herself, ill-favoured, wrinkled, pimpled, pale, red, yellow, tanned, tallow-faced, having a swollen juggler's platter face, or a thin, lean, chitty face, have clouds in her face, be crooked, dry, bald, goggle-eyed, blear-eyed, or with staring eyes, she looks like a squis'd cat, hold her head still awry, heavy, dull, hollow-eyed, black or yellow about the eyes, or squint-eyed, sparrow-mouthed, Persian hook-nosed, have a sharp fox-nose, a red nose, China flat, great nose, *nare simo patuloque*, a nose like a promontory, gubber-tushed, rotten teeth, black, uneven, brown teeth, beetle-browed, a witch's beard, her breath stink all over the room, her nose drop winter and summer, with a Bavarian poke under her chin, a sharp chin, lave-eared, with a long crane's neck, which stands awry too, *pendulis mammis*, "her dugs like two double jugs," or else no dugs, in that other extreme, bloody-fallen fingers, she have filthy, long unpared nails, scabbed hands or wrists, a tanned skin, a rotten carcass, crooked back, she stoops, is lame, splay-footed, "as slender in the middle as a cow in the waist," gouty legs, her ankles hang over her shoes, her feet stink, she breed lice, a mere changeling, a very monster, an oaf imperfect, her whole complexion savours, an harsh voice, incondite gesture, vile gait, a vast virago, or an ugly tit, a slug, a fat fustilugs, a truss, a long lean raw-bone, a skeleton, a sneaker (*si qua latent meliora puta*), and to thy judgment looks like a mard in a lanthorn, whom thou couldst not fancy for a world, but hatest, loathest, and wouldest have spit in her face, or blow thy nose in her bosom, *remedium amoris* to another man, a dowdy, a slut, a scold, a nasty, rank, rammy, filthy, beastly quean, dishonest per-adventure, obscene, base, beggarly, rude, foolish, untaught, peevish, Irus' daughter, Ther-sites' sister, Grobian's scholar; if he love her once, he admires her for all this, he takes no notice of any such errors or imperfections of body or mind, *Ipsa haec Delectant, veluti Balbinum polypus Agnae*; he had rather have her than any woman in the world.

Renaissance writers, when they speak of the imagination, are interested chiefly in its pathology, in hysteria and hallucination and the influence of the mind on the body. This is true of Montaigne's essay on the force of imagination, where an example of what may be called psychological vampirism comes from his own experience:

Simon Thomas was a great Physitian in his daies. I remember upon a time comming by chance to visit a rich old man that dwelt in *Tholouse*, and who was troubled with the cough of the lungs, who discoursing with the said *Simon Thomas* of the meanes of his recoverie, he told him, that one of the best was, to give me occasion to be delighted in his companie, and that fixing his eyes upon the livelines and freshness of my face, and setting his thoughts upon the jolitie and vigor, wherewith my youthfull age did then flourish, and filling all his senses with my flourishing estate, his habitude might thereby be amended, and his health recovered. But he forgot to say, that mine might also be empaired and infected.

At that stage of scientific development, scientific and occult explanations could be given of the same phenomena, and hysteria and hallucination might be explained either as mental disorders or as caused by witchcraft or diabolical suggestion. Burton gives a good deal of attention to such matters, though with a detachment toward them unusual in his age. He has read all the books about devils and witches, and has gathered from them that there is more theorizing than solid knowledge of the subject. He drops a hint that belief in their existence is convenient for an organized priesthood, and continues:

Many such stories I find amongst pontifical writers, to prove their assertions; let them free their own credits; some few I will recite in this kind out of most approved physicians. *Cornelius Gemma, lib. 2 de nat. mirac. cap. 4*, related of a young maid, called Katherine Gualter, a cooper's daughter, *anno 1571*, that had such strange passions and convulsions, three men could not sometimes hold her; she purged a live eel, which he saw, a foot and a half long, and touched himself; but the eel afterwards vanished; she vomited some twenty-four pounds of fulsome stuff of all colours, twice a day for fourteen days; and after that she voided great balls of hair, pieces

of wood, pigeon's dung, parchment, goose dung, coals; and after them two pound of pure blood, and then again coals and stones, of which some had inscriptions, bigger than a walnut, some of them pieces of glass, brass, etc., besides paroxysms of laughing, weeping and ecstasies, etc. *Et hoc (inquit) cum horrore vidi*, "this I saw with horror." They could do no good on her by physic, but left her to the clergy.

Burton is aware that he is describing a case of hysteria; what he is not sure of is whether it was the doctor or the patient who had it, and the reader is left with the feeling that Burton regards hysteria as a highly contagious illness.

We notice that the association of poetry, love and melancholy extends only so far. The lover's melancholy was of no more lasting importance in his life than a contemporary teen-ager's crush on a movie star: it was understood to be normal, even expected, of youth, and it had nothing to do with the serious business of marriage which was being arranged for him by his parents. Religious melancholy would turn instantly to the church, and be restored to normality by the sacraments and disciplines of that church. The kind of lyrical poetry produced by the lover's melancholy, too, was regarded as relatively minor poetry, appropriate to young poets learning their trade or to well-born amateurs who were merely using poetry as a status symbol. The major poet, who had advanced to the major, or heroic genres of epic and tragedy, was no longer inspired by melancholy but was working in the same general educational area as the philosopher, the jurist or the theologian. Thus the difference between the creative imagination of the professional artist and the practical skill of other professional men was minimized as far as possible. The great epic poet of Shakespeare's age, Edmund Spenser, includes in the second book of his *Faerie Queene* an allegory of the human body and mind, which he calls the House of Alma, and compares to a building. He explores the brain, and finds it divided into three parts. At the back of the brain is an old man called Eumnestes, good memory, who is concerned with the past. In the middle is the judgement, which is concerned with the present. In front is a melan-

choly figure named Phantastes, born under Saturn, concerned not so much with the future as with the possible, or rather with that uncritical kind of perception which cannot clearly distinguish the real from the fanciful:

His chamber was disappointed all within,
With sundry colours, in the which were writ

Infinite shapes of things dispersed thin;
Some such as in the world were neuer yit,
Ne can deuized be of mortall wit;
Some daily scene, and knowen by their names,

Such as in idle fantasies doe flit:
Infernall Hags, *Centaurs*, feendes, *Hippodames*,

Apes, Lions, Aegles, Owles, fooles, louers,
children, Dames.

The poetic faculty, it is important to notice, does not belong to this aspect of the brain: it belongs to the judgement in the middle, which also produces philosophy and law:

Of Magistrates, of courts, of tribunals,
Of commen wealthes, of states, of policy,
Of Lawes, of iudgements, and of decretals;

All artes, all science, all Philosophy,
And all that in the world was aye thought wittily.

Spenser had a disciple in the next generation, Phineas Fletcher, who produced a long didactic poem called *The Purple Island* (i.e., the body of man, traditionally formed of red clay). Half of it consists of an expansion of Spenser's House of Alma, an exhaustive survey of anatomy under the allegory of a building. Fletcher finds the same three divisions in the brain that Spenser found: he seems in fact to be merely cribbing from Spenser, but when he comes to Phantastes he makes a significant change:

The next that in the Castles front is plac't,
Phantastes hight; his yeares are fresh and green,

His visage old, his face too much defac't
With ashes pale, his eyes deep sunken been
With often thoughts, and never slackt intention:

Yet he the fount of speedy apprehension,
Father of wit, the well of arts, and quick invention.

Here, we see, Phantastes is the source of the arts, and of the creative aspect of the mind generally. The change may be sheer inadvertence, or it may mean that an actual change of emphasis is beginning to make itself felt on the level of informed but unspecialized opinion represented by such a poem. If so, it was not for another century that the change becomes generally perceptible.

The refusal of Renaissance thinkers to carry through the association of the creative and the neurotic temperaments is the result of a certain view of the world that was ultimately religious in origin. They thought of human culture and civilization as an order of nature or reality separable from, and superior to, the ordinary physical environment. This latter world is theologically "fallen"; man entered it with Adam's sin, and is now in it but not of it. He does not belong in physical nature like the animals and plants; he is confronted with a moral choice, and must either rise above nature into his own proper human home, or sink below it into sin, the latter a degradation that the animals cannot reach. The crux of the argument, however, is that the higher human order was not created by man: it was created by God and designed for man. Adam awoke in a garden not of his planting, a human world pre-established and ordered by a divine mind. In Milton's *Paradise Lost* Adam and Eve are suburbanites in the nude, and angels on a brief outing from the City of God drop in for lunch. But the City of God was there, along with another city in hell, long before the descendants of Cain started imitating them on earth. The corollary of this view was that the divine intention in regard to man was revealed in law and in the institutions of society, not in the dreams of poets. All ancient societies tend to ascribe their laws and customs to the gods, and, as the name of Moses reminds us, the Judaeo-Christian tradition is no exception.

We said at the beginning that the order of human existence represented by such words as culture and civilization has been established by man. This statement may seem obviously true now, but it is only within the last two centuries that it has been generally accepted. In earlier cen-

turies, when man was not regarded as the creator of the human order, it could even be disputed whether the arts themselves, poetry, painting, architecture, were genuinely educational agencies or not. Naturally the poets insisted that poetry at least was; for most, however, obedience to law, the habit of virtue, and the disciplines of religion were far safer guides than the arts.

Even those who were sympathetic to poetry, in fact even the poets themselves, placed strict limits on human creative power. The poet was urged to follow nature, and the nature he was to follow was conceived, not as the physical world, which could only be copied at second hand, but as an order of reality, a structure or system of divine ordinance. If one believes, as Sir Thomas Browne says in his *Religio Medici*, that "nature is the art of God," the art of man which follows nature does not transform the world but merely comes to terms with it. The social results of such a view are, of course, intensely conservative. Whatever is of serious importance, in the arts or elsewhere, serves the interests of the community of church and state; whatever is immature is also divisive and anarchic, and exalts the individual at the expense of society. The imaginary belongs to the melancholy individual and his whims; the imaginative is incorporated into a natural and human order established by divine decree.

The eighteenth century was the period in which this view of the imagination struggled with, and was finally defeated by, an opposed conception which came to power in the Romantic movement. At the beginning of the century, we have Swift, for whom established authority in church and state was the only thing in human life strong enough to restrain the desperately irrational soul of man. In this day the conception of "melancholy" was out of fashion, but another ancient medical notion of "spirits" or "vapors" rising from the loins into the head was still going strong. For Swift, or at least for the purposes of Swift's satire, all behavior that breaks down society is caused by an uprush either of digestive disturbances or of sexual excitement into the head. Swift's chief target is the left-wing Protestantism which in the seventeenth century had carried religious melancholy to the

point of replacing the authority of the Church with private judgement and had made a virtue even of political rebellion. But he finds the same phenomena in the political tyrant who substitutes his own will for the social contract, or the poet who allows his emotions to take precedence over communication. "The very same principle," he says, "that influences a bully to break the windows of a whore who has jilted him, naturally stirs up a great prince to raise mighty armies, and dream of nothing but sieges, battles and victories." In his *Discourse of the Mechanical Operation of Spirit* Swift says that three sources of abnormal behavior have been generally recognized. One is of divine origin, or revelation, one of demonic origin, or possession, and one of natural origin, which produces such emotions as grief and anger. To these he proposes to add a fourth, which is artificial or mechanical, and is essentially a transfer of sexual energy to the brain, where it produces lofty rationalizations of erotic drives. Or, as Swift says with a nice calculation of *doubles entendres*:

... however Spiritual Intrigues begin, they generally conclude like all others; they may branch upwards toward Heaven, but the Root is in the Earth. Too intense a Contemplation is not the Business of Flesh and Blood; it must by the necessary Course of Things, in a little Time, let go its Hold, and fall into Matter. Lovers, for the sake of Celestial Converse, are but another sort of *Platonicks*, who pretend to see Stars and Heaven in Ladies Eyes, and to look or think no lower; but the same *Pit* is provided for both; and they seem a perfect Moral to the Story of that Philosopher, who, while his Thoughts and Eyes were fixed upon the *Constellations*, found himself seduced by his *lower Parts* into a *Ditch*.

Swift is a satirist, and the attitude he takes is congenial to satire. For satire usually takes the point of view of sense: it requires a standard of the normal against which the absurd is to be measured, and, like sense, does not distinguish what is above it from what is below it. Such satire speaks with the voice of the consensus of society, and society can protect itself but cannot surpass itself. Hence a great age of satire like the early eighteenth century is likely to represent a culture which has

clearly defined views about madness, but feels fairly confident about its own sanity.

But even as Swift was writing there was beginning one of those great changes in cultural attitude, where we cannot see any origin or clear development of the change, but realize after a certain time that we are looking at a different world. As this different world, which came in with Romanticism, is essentially our world, we may take a moment to characterize some of the changes. Slowly but steadily the doctrine of the divine creation of the human order fades out, not perhaps as a religious conception, but as a historical and literal fact taking place at a specific point in past time. Man thus comes to be thought of as the architect of his own order, a conception which instantly puts the creative arts in the very centre of human culture. This new emphasis on the primacy of the arts in social life is clear in the statements and assumptions of the Romantic poets. The conception of nature as a divine artefact also fades out, and nature is thought of, not so much as a structure or system presented objectively to man, but rather as a total creative process in which man, the creation of man, and the creation of man's art, are all involved. For the Romantics, the poet no longer follows nature: nature works through the poet, and poems are natural as well as human creations. But if man has created his own order, he is in a position to judge of his own achievement, and to measure that achievement against the kind of ideals his imagination suggests. In Rousseau we meet the doctrine that much of human culture and civilization has in fact been perverse in direction, full of inequalities caused by aggression which have blotted out the true form of human community. This latter Rousseau saw as a society made up of a "general will" of free and equal individuals. And as society can speak only with the middle voice of sense, and cannot by itself distinguish the creative from the neurotic, we thus arrive at two typically Romantic, and therefore modern, conceptions.

First, any genuinely creative individual is likely to be regarded by society as anti-social or even mad, merely because he is creative. The association of the creative and the neurotic, being largely imposed on the

artist by society, places creative abilities under a curse, a capacity of misunderstanding that may blight or destroy the artist's social personality. Baudelaire symbolizes the creative spirit by an albatross, so superbly beautiful in its lonely flight, so grotesquely awkward and comic when captured and brought into the view of a human society. If we compare the target of Swift's satire, the melancholy individual creating his own poetry and religion out of a powerful erotic stimulus, with the figure of Byron a century later, we can see how completely cultural standards have reversed themselves. Byron like Swift was a satirist, but his satire does not speak with the voice of society against the erratic individual: it speaks with the voice of the individual against society, and assumes the individual's possession of a set of standards superior to those of society. This leads us at once to the second new conception: a society may judge an individual to be mad because that society is actually mad itself.

The notion that the whole of mankind has been injured in its wits as the result of Adam's fall was familiar enough, and is the basis for a great deal of satire, including that of Burton's *Anatomy*. In the seventeenth century the poet and dramatist Nathaniel Lee, a contemporary of Dryden, remarked when confined to a madhouse: "They said I was mad, and I said they were mad, and, damn them, they outvoted me." Fifty years later Hogarth, depicting the last stage of the rake's progress in the madhouse of Bedlam, sticks an enormous penny on the wall, indicating that the whole of Britannia is as mad as the rake. But the notion that madness can be a social disease affecting a specific society at a specific time is, I think, not older than the French Revolution. At that time those on one side of politics saw a whole society gone mad in revolutionary France; those on the opposite side saw an equally dangerous delusion in accepting the status quo. This social dimension of madness is, to put it mildly, still with us in the century of Fascism, Communism, and the parasites in the democracies who devote themselves to spreading hysteria.

Of all the great artists of the Romantic movement, the most interesting for our

present purposes is William Blake. Blake had practically no influence in his own day, and his reputation during his life and for long after his death was that of a lunatic. Gradually it was realized that he was a great creative genius, and that if the normal attitude regards him as a lunatic, so much the worse for the normal attitude. Blake himself had very clear notions of what constituted mental health and mental disease. For him, mental health consisted in the practice of the imagination, a practice exemplified by the artist, but manifested in every act of mankind that proceeds from a vision of a better world. Madness, for Blake, was essentially the attitude of mind that we have been calling sense, when regarded as an end in itself. The world outside us, or physical nature, is a blind and mechanical order, hence if we merely accept its conditions we find ourselves setting up blind and mechanistic patterns of behaviour. The world outside is also a fiercely competitive world, and living under its conditions involves us in unending war and misery. Blake's lyrics contrast the vision of experience, the stupefied adult view that the evils of nature are built into human life and cannot be changed, with the vision of innocence in the child, who assumes that the world is a pleasant place made for his benefit. The adult tends to think of the child's vision as ignorant and undeveloped, but actually it is a clearer and more civilized vision than his own.

Blake interpreted the ancient myths of titans, giants and universal deluges to mean that man had in the past very nearly succeeded in exterminating himself. He warns us that this danger will return unless we stop accepting experience and shift our energies to remaking the world on the model of a more desirable vision. This model Blake found in the Bible, but in his reading of the Bible he identifies God with the imaginative or creative part of the human mind. Thus his vision is quixotic in the strict sense, seeing the world about him as having fallen away from the vision of the Word of God, just as Don Quixote saw the world of his day as having fallen away from a vision of chivalry which he found in his library.

Don Quixote is of course another great Renaissance masterpiece in which imagina-

tion is treated primarily as diseased vision. It would be easy to see in Quixote a relatively harmless example of a very sinister type, one of the line of paranoiacs culminating in Hitler who have attempted to destroy the present on the pretext of restoring the past. But we soon realize that there is something better than this in Quixote, something that gives him a dignity and pathos which he never loses in his wildest escapades. He is followed by Sancho Panza, who is so completely an incarnation of sense that only one thing about him is mysterious: the source of his loyalty to Quixote. We get a clue to this near the beginning of the book. Quixote and Sancho meet a group of peasants who invite them to share their lunch of goat's milk and acorns. Acorns were traditionally the food of those who lived in the golden age, that legendary time of simplicity and equality which has haunted so many discussions of human culture from Plato's *Laws* to Rousseau's *Social Contract*. Don Quixote is prompted by the sight of acorns to make a long speech about the golden age, first inviting Sancho to sit beside him, quoting from the Bible the verse about the exalting of the humble. He says that it is his mission to restore the golden age, which is, incidentally, exactly what Blake said the purpose of his art was. True, elsewhere he tells Sancho that the golden age would soon return if people would only see things as they really are, and not allow themselves to be deluded by enchanters who make giants look like windmills. But we can see that Quixote's obsession about chivalry is not so much what he believes in as what he thinks he believes in, a childish world where dreams of conquered giants and rescued damsels keep coming true, and which has thrust itself in front of his real social vision. This latter is a vision of simplicity and innocence, not childish but childlike, the element in Quixote that makes him courteous, chaste, generous (except that he has no money), intelligent and cultured within the limits of his obsession, and, of course, courageous. It is the solid core of moral reality in the middle of his fantasy that holds the loyalty not only of Sancho but of the readers of his adventures. For this wistful sense of a golden age, lost but still possible, the child's

vision which the Gospel tells us is so dangerous to lose, is something that makes Quixotes of us all, and gives our minds, too, whatever dignity they may possess.

In Part Two of the book, Quixote and Sancho come into the dominions of a duke who has read Part One, and who, to amuse himself, makes Sancho the governor of an island. We are perhaps less surprised than he to learn that Sancho rules his island so honestly and efficiently that he has to be pulled out of office in a hurry before he starts to disintegrate the Spanish aristocracy. We are even less surprised to find that Quixote's advice to him is full of gentle and shrewd good sense. The world is still looking for that lost island, and it still asks for nothing better than to have Sancho Panza for its ruler and Don Quixote for his honoured counsellor.

In the fifth book of Wordsworth's *Prelude*, the great epic poem in which he describes the growth and formation of his own very modern mind, Wordsworth deals with the influence that his reading has had on him. As a student he was interested in mathematics and literature, and the literary works he particularly mentions are the Arabian Nights and *Don Quixote*. He tells us that he (at least we may assume it was he) fell asleep while reading *Don Quixote*, and had a strange dream. He saw an Arab horseman, who was also Don Quixote, riding over the sands of a desert carrying a stone and a shell, which were also books. The books were Euclid and an unnamed book of poetry: in other words they were the keys to the worlds of words and numbers, the two great instruments that man has invented for transforming reality. The Arab, or "Semi-Quixote" as Wordsworth calls him, is fleeing from some unimaginable catastrophe, which the poet calls a deluge, and is going to bury these two books to keep them safe until the disaster is past. Wordsworth says that he often reverts to this dream, and that he has felt

A reverence for a Being thus employ'd ;
And thought that in the blind and awful lair
Of such a madness, reason did lie couch'd.
Enow there are on earth to take in charge
Their Wives, their Children, and their virgin
Loves,

Or whatsoever else the heart holds dear ;
Enow to think of these ; yea, will I say,
In sober contemplation of the approach
Of such great overthrow, made manifest
By certain evidence, that I, methinks,
Could share that Maniac's anxiousness, could
go
Upon like errand.

Perhaps in the age of the useless bomb-

shelter it may be easier for us than it was
even for Wordsworth to understand that if
the human race is to have any future at all,
it can only obtain it through a concern for
preserving its powers of creation which it
will be difficult, if not impossible, to dis-
tinguish clearly from a "Maniac's anxious-
ness."

A SURVEY OF MENTAL DISEASE IN AN URBAN POPULATION

VII. AN APPROACH TO TOTAL PREVALENCE BY RACE

BENJAMIN PASAMANICK, M.D.¹

For centuries men have sought and described biological differences between various groups—national, religious and ethnic, class and caste, and in and out groups. All too frequently observed or imagined biological differences, however minor, have been used to justify hatred, oppression, exploitation and even genocide. Recent and present history provide ample testimony to the potency of such doctrines.

The unfortunate abuse by mankind of observable differences between groups does not, however, justify neglecting the scientific importance of studying, understanding and even predicting the consequences of such differences. With the development of newer and more reliable epidemiologic and ecologic tools, more recent scientific investigations have sought psychological and sociocultural mechanisms for every kind of biological and related type of difference between groups. This has been an extremely fruitful area of research, with the great majority of studies now tending in the direction of finding fewer and fewer innate differences between groups.

By far the most commonly studied group in this country has been the Negro. This is hardly surprising in view of his unique history, the passions aroused by this history, his condition in life, the recent assertions of his rights to the American dream, and the fact that he constitutes the largest and most highly visible minority group. This unique combination of circumstances has consequently attracted researchers with varying combinations of motivations and resulted in findings that probably more often than not represent a justification of the investigator's own attitudes on the subject.

This paper attempts to deal with the problem of the prevalence of mental diseases among an urban population of nonwhites and to compare, as dispassionately and objectively as possible, these rates with

those for whites.

The earliest census which contained data on white and nonwhite rates into mental institutions was the 1840 census. The rates contained therein indicated that Northern nonwhites had substantially higher rates than Southern nonwhites. Pro-slavery protagonists found this disparity grist for their mill(1). They concluded that this discrepancy indicated two things. First, that the innately inferior Negro could not withstand the stress of competition in a comparatively freer society. Second, that nonwhites were better understood and treated in the South and hence, the lower insanity rate. The fact of the matter was that gross inaccuracies had occurred in the census data. For example, Negro rates in some communities were so high that they actually exceeded the total Negro population in the community. The physician who had originally published a paper based on these rates eventually voluntarily retracted his published statements(2). Despite these inaccuracies, and the obvious biases inherent in using first admissions for incidence rates, these and similar data continued to be used.

By 1880, the issue of white versus nonwhite rates and regional variations in the latter was broadened to include foreign versus native-born rates. The stimulus for the latter, of course, was the increasing entry into this country of Irish and Catholic population and the hostility this immigration aroused. The 1880 census stated, for example, that, "the extraordinary ratio of insanity among the foreign-born has attracted wide attention." The report continued by asserting that "the question of age has a bearing upon the comparative number of the insane who are of native and of foreign birth" and that "the difference disappears, in large measure, when, instead of comparing the number of insane with the total population, we compare it with the population above the age at which insanity ordinarily occurs, that is to say above the age of 15 years"(3).

¹ Professor of Psychiatry, Ohio State University and Director of Research, Columbus Psychiatric Institute and Hospital.

In time the immigration question, because of increasingly severe restrictions on the number who could enter, became academic(4). The question of the existence of a racial disparity in rates remains, and if anything, is as heated as ever. As late as 1957 Wilson and Lantz published a paper on this subject which received a great deal of publicity(5). They contended in this paper that there has been a tremendous increase in the nonwhite mental hospital admission rate in the past 40 years and attempted to interpret this increase in terms of the "uncertainties of the Negro race as they cross from one culture to another." Wilson and Lantz state that, "Cultural changes which are forced on people against their will, by fiat or by authority from outside or above, have been found by the experts of the U. N. to produce major disturbances of mental health." They also quote Margaret Mead to the effect that "the change must be made slowly" and that in the recent past little has been done "to protect the Negro or the white man as this change in relationship is brought about," that is, as the process of integration proceeds.

These conclusions imply a culture shock or cultural breakdown theory and are therefore largely inapplicable to the Negro who shares the same cultural heritage as other Americans. The fact of the matter is that there is almost no vestige of African culture left among the American Negroes. Rarely has such complete deculturation and reculturation ever occurred in world history. To implicitly liken the primitive African tribesman to the American Negro in a culture shock context is about as realistic as comparing a middle class, urban dweller undergoing analysis to his preliterate ancestors.

Wilson and Lantz also take other undue liberties in interpreting their data. For example, they cite the higher rate of jail commitments for Negroes in Virginia to show "that the Negro community exhibits the other characteristic of a frustrated community, namely crimes of aggression." Not a word is said about the legal and enforcement problems of majority implemented laws or any of the many other factors which sociologists and criminologists have pain-

stakingly documented over the years. Finally, Wilson and Lantz cite the high rate of nonwhite admissions to state hospitals in the North to imply that it is the unstable nonwhites who are likely to migrate North. The fact that nonwhites in the North are overwhelmingly urban while those in the South remain predominately rural or small town dwellers and the implications of this seem to them of no concern. Nor, by way of illustration does the relative availability and adequacy of hospitals in the two regions seem to mean much to them.

Any number of such items can be extracted, discussed and questioned. These, and the other less questionable findings, all depend on the use of first admission data. This paper hopes to overcome some of these difficulties by examining prevalence rates by race using methods described below.

ORIGINS OF DATA

The data to be presented on the prevalence of mental disorders in Baltimore were derived from 4 sources. These sources constitute an approach to a relatively complete assessment of the reported, unreported, and institutionalized cases of mental disorder.

Data on the prevalence of these chronic disorders among noninstitutionalized persons were in part derived from the Commission on Chronic Illness which conducted a questionnaire investigation supported by clinical evaluations of a large number of carefully selected persons in the community.

1. *The Commission on Chronic Illness Study*. The Commission on Chronic Illness, an independent agency founded jointly by The American Medical Association, the American Hospital Association, the American Public Health Association, and the American Public Welfare Association in 1952-1955, conducted a survey of the prevalence of chronic disorders in Baltimore. The research design and references to the various phases of the study, the sample characteristics, and the biases and limitations are detailed in the fourth volume of *Chronic Illness in the United States*(6). The data included in this report are based on a stratified sample of approximately 1,200 individuals, of whom 809 responded and were given

thorough clinical and laboratory evaluations at the Johns Hopkins Hospital, as well as consultations with the relevant specialists when necessary. By the proper application of weights, the 809 evaluatees were found to be distributed almost identically by age, color, and sex with the Baltimore population, so that the rates to be described within certain limitations may be deemed representative of the noninstitutionalized Baltimore population(7-10). A miscellaneous group of childhood behavior disorders, mild mental defect, alcoholism, and other minor personality or behavior difficulties which had an adjusted rate of 15.2 per 1000 is excluded from this report because it was deemed that the judgments of both examining physicians and psychiatrists were probably not very reliable, and better sources of data exist in other studies.

2. *Study of Prematures.* In another study there were 500 prematurely born infants and an almost similar number of full term controls born in Baltimore in 1953 and examined at approximately 40 weeks of age at the Johns Hopkins School of Hygiene(11). This sample was adjusted to the Baltimore infant population by controlling for the rates of prematurity, race, sex, and socioeconomic status. On this basis, a total rate of 15 per 1000 mentally defective infants was derived(12). These are the organically impaired mental defectives and do not contain among them the socioculturally and educationally retarded children. Inclusion of the latter would result in the estimates of 4% to 14% found in the school-age population.²

It might be added that re-examination of the children at 3 years of age confirmed these rates and also indicated the high reliability of the infant examination procedures. While the prevalence rate of 15 per 1000 is for a pre-school age population, because little or no improvement in intellectual functioning can be expected for this population, it is not too unsafe to use

it for the total population. Since a number of these cases may be expected to be removed by death, clinical judgment leads us to believe that the rate constancy of this diagnostic category will result from the addition of brain-damaged individuals who at later ages will be pushed down into the definitely defective and severely impaired group by the interaction of sociocultural and organic factors.

3. *Institutional Rates.* A third source of data on mental disorders were those Baltimore residents hospitalized as of June 1, 1954, and consisting of all of the individuals in the 3 state mental institutions admitting patients from Baltimore and from private hospitals. It was unfortunate that hospital census recording did not include city of residence, so the data had to be secured laboriously by hand from the hospital records.

4. *Veterans Administration Facility Rates.* A frequently ignored source of data, particularly when institutionalized cases are considered, are the Veterans Administration facilities. This is a common source of bias, particularly when sex and age differences are considered. We were fortunate in being able to use the data of a 50% systematic sample of the Baltimore residents of the Veterans Hospital serving the Baltimore area.

FINDINGS

1. *Psychoses.* The white and nonwhite rates for the psychoses, which are presented in Table 1, would appear to refute the Wilson and Lantz hypothesis. These rates indicate that the nonwhite state hospital rates are indeed higher than those for whites. For the Baltimore population the nonwhite rate is 75% greater than the white rate. However, this is not by any means the whole story. White rates exceed nonwhite rates in both private and V.A. hospitals. The biggest discrepancy of all occurs in the noninstitutional rate. At this level, the white rate is over ten times as great as the Negro rate. Assuming the equal reliability of the data obtained from all of these sources—and clearly this is the most parsimonious assumption—the overall rate for whites in Baltimore is 9.46 per 1000 while the Negro rate is not significantly different

² Since these sociocultural retardates are not mentally ill or primarily medical problems, it was deemed inadvisable to include them in any total prevalence picture. Infancy is thus the ideal age during which organic impairment can be differentiated from the psychologic effects of an impoverished and deprived environment.

TABLE 1
Prevalence of Mental Disorder in Baltimore as a Rate per 1000
Persons by Diagnosis, Race, and Source of Data

DIAGNOSIS	NON-INSTITUTIONAL				STATE HOSPITALS †				PRIVATE HOSPITALS †				V.A. HOSPITALS ‡				TOTAL	
	TOTAL RATE	NO. OF CASES	RATE		NO. OF CASES	RATE	NON- WHITE	NON- WHITE	NO. OF CASES	RATE	NON- WHITE	NON- WHITE	NO. OF CASES	RATE	NON- WHITE	NON- WHITE	TOTAL RATE

at 7.04 cases per 1000. On the face of it, therefore, the lower Negro rate clearly vitiates the labored explanations of Wilson and Lantz.

Even when the rates for psychoses are adjusted for age, as they should be, because, as Wilson and Lantz point out, "Negroes die younger," the total prevalence rate is still higher for the white Baltimore population. Finally, it should be noted that the psychoses are among the easiest to diagnose of the mental disorders. This being the case, it is most unlikely that noninstitutional Negroes went unrecognized by the team of evaluators in the community. On the contrary, clinicians have stated that because of the inability of white psychiatrists to comprehend the nuances in the Negro subculture and the behavior of individuals socialized in this subculture, there is the tendency to over-diagnose psychoses among Negroes (13).

From all of this it follows that the discrepancy in prevalence rates is probably small, if there is a disparity at all, and it is as likely to favor the nonwhites as the whites. The higher noninstitutional white rates are offset by the higher nonwhite state hospital rates. Two questions follow from this. How may the higher nonwhite institutional rates be explained and conversely, what accounts for the greater white noninstitutional rates? In effect, these questions suggest the answers.

The lower class population—Negro and white—living under adverse economic and social conditions and with less stable family ties is simply in no position to maintain, care for and tolerate a disturbed and disturbingly ill individual. Such individuals consequently are institutionalized. This applies as already noted to lower class persons in general. Since the Negro population, relative to the white, is overwhelmingly lower class, it follows that nonwhites will be proportionately institutionalized. By the same token, the ability and willingness and wherewithal to maintain a sick person in the community under medical supervision or to send him to a private institution is positively related to class. The white population is therefore likely to send relatively fewer cases to state hospitals. This would appear to be a simpler, more logical and

more realistic explanation. In the same vein, it would be easier to tolerate a disturbed person in a rural setting than in an urban and highly complex one. Would not then the higher Northern institutional rates for nonwhites be a function of the urban setting, including the greater likelihood of being diagnosed as psychotic?

2. *Psychoneuroses*. Racial differences in rates for the psychoneuroses are almost wholly dependent upon an examination of noninstitutional cases. Few psychoneurotics are sent to state hospitals. From Table 1 it is readily apparent that the psychoneuroses rate is over twice as high for whites as for nonwhites. The exact rates per 1000 are 62.29 and 27.55 respectively. This rate discrepancy occasions little surprise. The class explanation above would explain part of the disparity. Upper class persons are more likely to be diagnosed as psychoneurotics and lower class persons as psychotics or personality trait disturbances. Again, as noted earlier, white, middle class examiners are, for cultural reasons and familiarity with symptoms, more likely to be aware of psychoneurotic manifestations in whites. There is also the problem of the channeling and content of neurotic manifestations and subcultural variations thereof. Certain behaviors—anxiety, hostility and the like—may take different forms and thereby go under detected in groups removed from one's own. The different meanings which attach to the same gestures, words, and symbols on a subcultural basis may also play some role in this discrepancy.

3. *Psychophysiologic Autonomic and Visceral Disorders*. As in the instance of the psychoneuroses, psychophysiologic autonomic and visceral disorders are over twice as frequently encountered in whites as in nonwhites. From Table 1, the rates per 1000 population are 43.70 and 17.70. Institutional rates for these disorders are negligible.

In interpreting this finding, the same basic *post hoc* explanations as for the psychoneuroses are suggested. In addition, it is very probable, based on sociological evidence, that nonwhites as lower class persons are less likely to report symptoms which enter into this diagnosis. The lower class emphasis on toughness and its lesser aware-

ness of an emphasis on the significance of psychophysiologic disturbances undoubtedly accounts for some of the difference in rates. This should apply even more strongly to white and nonwhite females.

4. *Acute Brain Syndromes.* This category of disease is almost wholly confined to the consequences of alcoholism. Institutional rates are nine times greater for nonwhites as is shown in Table 1. Whether this reflects true prevalence rates is again questionable. The extent to which these rates are influenced by the ability of the white population to receive private treatment in general hospitals and the lesser ability of nonwhites to do so is unknown. The opposite results would be obtained, it should be stressed, if membership in Alcoholics Anonymous was sampled. To restate and reemphasize the problem, all of these rate disparities may represent nothing more profound than differential access to private versus public treatment.

5. *Mental Deficiency.* Referring again to Table 1, it will be seen that nonwhites have a 60% higher rate than whites for mental deficiency in Baltimore. The figures are 21.30 per 1000 nonwhites and 13.20 per 1000 for whites. This higher nonwhite expectancy has been reported in almost every comprehensive study on the subject. The lower rates for Negroes found in Virginia institutions reflect either a lack of facilities for nonwhite mental defectives or the higher percentage of rural nonwhites since mental defectives like mental patients are much more readily cared for in rural areas, or some combination of both of these factors.

In previous investigations we have attempted to ascertain the probable causes for higher mental deficiency rates among Negroes. We have found that mental deficiency is associated with prematurity and complications of pregnancy (14). The latter, in turn, are largely determined by socioeconomic variables so that brain damage and neuropsychiatric disorders stemming from a continuum of reproductive casualty should more likely be encountered in the lower socioeconomic groups (15).

SUMMARY

This paper reported the results of a series of concurrent investigations in Baltimore dealing with the prevalence rates for various psychiatric disorders in the white and nonwhite population. The findings based on a community survey, and state, private and V.A. hospital rates indicate that the white population has the higher rates for the psychoses, psychoneuroses, and the psychophysiologic-autonomic-visceral disorders. Nonwhite rates are higher for the acute brain syndromes and for mental deficiency.

An attempt is made to explain these variations and to refute the conclusions of a previous study by Wilson and Lantz in Virginia.

THE SCIENTIFIC STUDY OF MASS MEDIA EFFECTS¹

FREDRIC WERTHAM, M.D.²

Max Born, one of the greatest and most conscientious atomic physicists, who received the Nobel prize in 1954, recently made an important pronouncement. He said, there is now "a dark shadow over everything," and he specified two facts: the methods of mass destruction and the corruptive influence of mass media, especially television.

Atomic fallout is being widely studied. In the field of psychological fallout from the mass media, however, clichés and misinformation abound. It is a characteristic of psychogenic factors that they may be activated, modified or inhibited by groups of other factors. That is one reason why the study of the effects of mass media (to which a majority of the population is directly or indirectly exposed) is so important. Television is a qualitatively new factor, unknown to Kraepelin, Freud or Bleuler, just as nuclear energy was unknown to the classical physicists.

The problem of harmful influences on the young and the methods of guarding against them changes in different periods. At the present time the most important event in this field is the appearance of a number of books which tend to minimize or deny the effects and confuse the issues. This is done in the name of science and the conclusions have been accepted by both laymen and behavioral scientists as "solid research." Therefore it is necessary to determine with regard to mass media effects what scientific methods are applicable and can give valid results.

The book most widely quoted on both sides of the Atlantic is *Television and the Child* by H. T. Himmelweit, *et al.*(1). It comes to the conclusion that television does not affect children significantly one way or another. Careful study of the evidence,

however, shows that this elaborate report shows nothing of the kind. It is just another of the generalizations to the effect that the child's responses are determined entirely by the "basic" personality of the child and not by the stimulation of the screen.

The children *were not examined*. They just filled out formal questionnaires—which is not the way to get true and intimate facts from a child. The book relies on statistics based on individual answers to questions, without considering the whole child. Individual facts are arbitrarily selected, separated and considered completely outside the concrete situation of the child and his family. As far as negative effects are concerned, attention is centered on what is "frightening" or "disturbing" to the child. From a mental health point of view, these are neither the only nor even the most important bad effects.

The report is particularly misleading when it takes up the effect on children of the violence in Western programs. It says that this violence is abstract and stylized and therefore innocuous and "readily acceptable." This pronouncement indicates the difference between the adult's offhand acceptance of what he *thinks* the child gets from television and the actual reaction of the child. It is a typical adult response, and is not how *children* see it. For example, the report states that if the victim who has been shot clutches at his stomach, that merely means to the child that he has been shot from the front! Many children have told me what it means to *them*: that the man is shot in the stomach because that is one of the places where it hurts most.

This book says of Westerns that "guns are generally ineffective." As proof: in one Western many shots were fired "yet no one was killed and only one man was seriously injured, a second man slightly." Children—and I agree with them—do not consider this "ineffective." The report also states that the villains in Westerns kill fewer people than do the good guys. This,

¹ Presented in part at the Conference on the First Amendment sponsored by the magazine *The Catholic World* in the program "The Effects Controversy," Oct. 1961.

² Consultant Psychiatrist, Queens Hospital Center, N. Y.

they say, "may worry humane persons; for children it has less significance . . ." I have found that in the long run this affects children profoundly.

It seems that one of the main preoccupations of this book is to discount the idea that there are any TV-inspired or TV-directed antisocial responses by children as a result of what they may have seen on the screen. Because children know that the ending will be happy "the violence does not matter!"

When this report appeared it was already out-of-date. The screen had not yet become, as one British critic put it, "littered with dead cowboys." Moreover it does not apply, then or now, to American children who are exposed to much more and worse screen mayhem.

The many tables that stud the book look persuasive. The book's message is very truly summarized in a popular medical column by Dr. Theodore van Dellem: "Dr. Himmelweit blames the personality and immaturity of the child for many of the bad effects attributed to this medium." Is it scientific to use the immaturity of the child to explain away the irresponsibility of the adults who produce the unhealthy programs for them? Bishop James A. Pike, who presented Dr. Himmelweit on his television program in California, summed up her main conclusion: "We have to tailor television programs to the particular child." That misses the very essence of television, which makes a visual impact on a *mass audience* of millions and cannot possibly be tailored to the individual child.

A book very similar in method, conclusion and influence is *Television in the Lives of your Children* by Wilbur Schramm, et al. (2). Here we find the old generalizations for which no research would have been necessary: What a child "takes" from television depends on the "needs" of his personality; television is so varied that it meets "all sorts of needs"; only children already "maladjusted" (that so conveniently vague term) are affected; "violence won't hurt your child anyway if the child is psychologically healthy" (thus disregarding entirely the long-range sleeper effects revealed by my clinical studies, such as instilling callousness, loss of sympathy, be-

coming accustomed to brutality and falsely linking sex with violence). We are asked to eradicate from our thinking the "stereotype of the Big Media and the Little Me." This is far from being a wrong stereotype; the contrast between the immensely powerful mass media and the individual family and child is one of the most essential facts of our present social existence. Psychological conclusions become invalid if we disregard it.

This is another book of statistics based on questionnaires, some filled out "in the classroom" by many children, some filled out for younger children by their parents. They provide unlife-like data which do not give the whole picture and which no amount of statistics can redeem. Although the author states that he "made use of all the other research" he could find, he departs from scientific custom (as does Himmelweit) by not mentioning contrary findings either in the text or in the bibliography. His book also obscures the important fact of grave concern to physicians, that very many young children do not get enough sleep because of watching late television shows. How do these authors dispose of this well-established clinical fact? Schramm says that children who watch television "on the average" go to bed only 13 minutes later than other children; Himmelweit says 10 to 20 minutes later. Such misuse of statistical average figures gives a totally wrong impression. It is like claiming that there are no multimillionaires or paupers by using the computation of the average American income. We are concerned here with paupers, and as far as sleep is concerned there are many of them.

At the end of the book there is "A Psychiatrist's Comment on the Effects of Television" by Lawrence Z. Freedman. It is all about the child and not about television—all theory instead of clinical fact. We are told that "the daydreams of most (*sic!*) children would make the fiercest television show seem tame." I have examined many children of many sorts for many years, and supervised their examination in clinics. I have never found any child who had daydreams of, for instance, cutting out a beautiful girl's tongue, or having a man

hanged by his feet over a fire with his head in the flames, unless it was suggested to him from the outside. Nor can I confirm the statement that "stable children from reasonably harmonious homes" are "unaffected."

Despite its dubious scientific value, this book has had tremendous influence. It is on the shelves of the most well-meaning people, in child guidance, law and theology. It has received exuberant reviews, from *The New York Times* ("excellent," "well-documented," "a standard work," "exhaustive research") to the *Daily Worker* ("most careful," "exhaustive study," "sound advice," "children get out of TV what they bring to it"). A statement in the *London Times* links the two books together and says that "these two reports have laid the groundwork for future policy, both among the networks and in the home."

So the home, which in pre-electronic times afforded the child protection, is invaded on two fronts: by bad television programs which influence the children and by slanted books about them which influence the parents.

The declared aim of *The Effects of Mass Communications* by Joseph T. Klapper(3) is to "integrate" published research on the subject. The blurb speaks of "scholarly analysis," "independent analysis of research" and calls the book a "basic reference work." What does it tell the teachers and others connected with child guidance and education to whom it is distributed? The author comes to the conclusion that "nothing is known about the relationship, if any (*sic!*), between the incidence of violence in media programs and the likelihood that it will produce effects." He amplifies: "absolutely nothing (*sic!*) is known regarding the relative potential of varying amounts of stimuli. The statistics of violence shine conspicuously in a standardless void."

Actually we are confronted in the mass media with a display to children of brutality, sadism and violence such as the world has never before seen. At the same time there is such a rise of violence among our youth that no peace corps abroad can make up for the violence corps at home. If, as this book tells us, we know "absolutely nothing" about it, we would be

scientifically in a bad way indeed.

Three other books can be cited: the chapter on mass media in the book *Juvenile Delinquency* edited by Roucek(5) is a survey which also recognizes only the quantitative and completely equates scientific with statistical. The book *Adolescent Aggression* by Bandura and Walters(6) leaves out any consideration of mass media entirely. A *Study of Murder* by Stuart Palmer(7), subtitled "A Scientific Study," is a statistical study with a control group and with numerous graphs and tables. Although one of the subjects, a youth who killed a 4-year-old girl, specifically brings up screen violence, mass media are not considered. A review in *The Nation* says that this book "must be welcomed the world over." One of the book's main conclusions is that "the typical murderer was white, Catholic, and neither the oldest nor the youngest child in the family." This statement is no more preposterous than the conclusions in the Himmelweit book and the others like it. The method is the same.

The fact that all the research in these books was financed by Foundations or research agencies indicates a currently approved trend.

The error of these and similar publications is their method. That is why they arrive at negative conclusions about mass media effects. The term *statistical* does not embrace all science. The statistical-questionnaire-control-group method is unsuitable for these intricate problems. Consequently it is bound to lead to wrong results. While it is alleged to be objective, actually it is very subjective. The statistical results offered us are based on arbitrary assumptions. Questionnaires are a Procrustes bed and they do not elucidate the whole picture. A little boy who was asked if he believed in God answered truthfully: "Sometimes." You would have to know a lot more about this child before being justified in drawing any conclusions. But in the hands of current users of the statistical-questionnaire method this sort of answer would lead to establishing groups of believers, non-believers and undecided, from which percentages would be figured out. Such primitive categorical classifications abound in the literature. To give a child a set of questions is practically

the opposite of a careful clinical examination.

Control cases that would be comparable units, as in physics or biology, do not exist in such a complex field as mass media. No statistical refinements can overcome the errors contained in the data. How can you possibly find in New York City 200 children who have seen television and 200 sociologically and psychologically strictly comparable children who have not? Some children do not have a TV set because of the low economic status of their parents; others have none because of affluent intellectual parents who consider themselves too sophisticated to permit sets. Yet in statistics both would appear in the same control group. It is a fallacy to think that findings are not scientific unless they can be expressed in a graph and must have very large numbers. In none of Freud's works are there any statistics. If you demand mathematical precision you could not even say it is bad to covet your neighbor's wife: nobody has ever done a statistical study on that with control cases.

We must recognize "the frailties of the questionnaire method," as Dr. Clarence B. Farrar put it. The *clinical method* is what is needed for any truly scientific study of mass media effects. There is no substitute for a thorough clinical psychiatric examination of actual cases.

The clinical method includes a study of the whole child, a diagnostic evaluation of his personality and emotional life, his thinking, his background, his real satisfactions and dissatisfactions, the application of psychodiagnostic tests and—most important—a follow-up of his further development and response to guidance and therapy. You must gain the confidence of the child. The question of mass media effects is introduced in such a study only indirectly, unobtrusively, as part of the whole group of factors that motivate and influence a child. What you need are spontaneous responses. In very young children playroom observation is of the greatest help. You do not have to ask the children questions; you can watch whether, when and how they fight with other children. I have seen real wars in the nursery, with Superman, Popeye and the Three Stooges as the emulated heroes.

The different media are very different in their aesthetics and their impact. The relations of the printed word to the human mind are not the same as those of the visual image or the moving image accompanied by speech. The content of crime comic books, with which I started my mass media research³ originally, was easier to analyze and correlate because they could be kept indefinitely(4). To monitor many television programs for children's viewing hours, and keep records of them, is more difficult.

What is the function of television? It serves five purposes: entertainment, information, education, advertising and propaganda. In all of them it has been eminently successful. My clinical studies of over 200 unselected cases led to the conclusion that our younger generation is getting more and more teledirected(4, 8-10). My material includes a sampling of all kinds of cases, from the mildest attitude changes to the 12-year-old boy who stabbed his sister in the breast with scissors. Those who do not see such cases cannot draw valid conclusions. The influence of mass media varies greatly in degree and kind with different children and adolescents and their concrete life situations. In general, there is a tendency to stereotype emotions at the expense of the emotional spontaneity of the individual. The relentless commercialism and the surfeit of brutality, violence and sadism has made a profound impression on susceptible young people. The result is a distortion of natural attitudes in the direction of cynicism, greed, hostility, callousness and insensitivity. This may express itself in the individual in overt acts, in fantasy, in dreams, in subtle personality changes, in a lowering of inhibitions or an alteration in the threshold of resistance to all kinds of injurious influences. Greed and sadism are perpetuated where they exist and aroused where they do not. Doing wrong means getting caught. Harmful mass media influences are a contributing factor in many young people's troubles.

To make such clinical observations one has to start not without premises, but with premises that are correct. A realistic conception of what a child is is necessary.

³ Within four years after the publication of *Seduction of the Innocent* 24 of 29 crime comic publishers went out of business.

Without thorough examination we cannot tell what child is susceptible and which is not. Children—all children—are impressionable. Ilg and Ames of the Gesell Institute at Yale state in their column "Child Behavior" that many perfectly normal (*sic!*) children, particularly around 7-8 years of age, experience spontaneous (*sic!*) love for blood, murder and torture. (In other words, they are born that way.) To start from such a false premise *must* lead to wrong conclusions—and, what is worse, to *wrong observations*.

Another misconception is the over-simplified generalization that we can start with a sharp *a priori* distinction between normal, stable children and "emotionally disturbed" and unstable ones. The term *emotionally disturbed* needs at least some clinical psychiatric underpinning. Otherwise it is just name-calling. To lump all normal children together means to assume a monotype standard and disregard the fact that different types of healthy children have different degrees of susceptibility. The normal child is alleged to be invulnerable, the abnormal child vulnerable. This misconception is so widespread that it seems almost impossible to eradicate it. It is not only the abnormal and maladjusted child, however, who can learn—and be seduced. Every sex offender knows that. Normal children are not inaccessible. They learn; they are sympathetic, interested; they can be taught bad as well as good.

It is frequently contended that whatever the effects of the bad features of mass media, they are not a "basic" cause, not an immediate, direct, primary factor. This is too mechanistic a conception of causality. Such a term as *basic* is purely subjective and pretentious. We do not know the basic cause of heart attacks, but we know a great deal about contributing factors. Who knows the "basic" cause that leads men to kill, steal, pray or vote? Of course "the makers of mass media have not created the appetite for violence," as is so often stated. Nor have peddlers of pornography to children created the sex instinct. But it makes no fundamental difference in our stage of knowledge if a cause is not "immediate" but remote, not "primary" but secondary, not "direct" but indirect. What is important is that

without this contributing factor the harmful effect would not have taken place (pathogenic effect) or at least not in that form (pathoplastic effect). The much-used term "triggering" to describe mass media effects is just evasion. A concrete clinical analysis of all causal connections is necessary. The schematic distinction between causal and contributory does not hold in the world of emotion. In mental life, all contributory factors have to be regarded as causal.

The objection is sometimes raised that mass media violence cannot be isolated and is merely a symptom of our general social life and not a cause. That is again too simplistic and mechanical an idea of causality. Something may very well be a symptom and at the same time a cause. Socially, mass media violence is a symptom; individually, it may be an operative cause.

Clinical observation with emphasis on follow-up indicates that the long-range effects are the most important ones. If a child or an adolescent spends some 5 hours a day before the television screen—and many do—and sees there in half an hour more violence than an adult sees in a lifetime, the effects may not show up on a questionnaire. I have found that does not mean they are not there. As one of the most realistic students of wayward youth, Father Mario Borelli, expressed it: "A child's mind is like a bank. Whatever you put in you get back ten years later with interest."

The test of science is prediction. On the basis of my studies I predicted *fifteen years ago* that more and more brutal violence would be committed by younger and younger age groups. This was met then with disbelief. Now it is common knowledge. We are raising a generation of violence-worshippers. "Violence?" one of the young Brooklyn thrill-killers told me, "It is everywhere." Mass media have helped to create and foster the belief that brutality is an expedient regulator in all social relationships. There is a real danger that today's fiction will become tomorrow's documentary. The clinician will have to take the influence of mass media into account for better understanding of the individual and for the public health aspects of psychiatry.

THE PSYCHIATRIST'S ROLE IN THERAPEUTIC ABORTION : THE UNWITTING ACCOMPLICE ¹

SIDNEY BOLTER, M.D.

Since the days of World War II, the psychiatrist's influence in American life has persistently broadened. We are called upon to give opinions on all sorts of matters ranging from the purely medical through the psychological to the social, economic, and even political. With better salesmanship, our image has changed and has brought a gradual, but definite acceptance by the general public and by our colleagues in other parts of the medical profession. With this increasing acceptance has come increased responsibility. We are asked to assist in making decisions which not only are of prime importance to our patients but also may have a widespread effect on the community-at-large.

The topic of this paper concerns one of the areas in which we are frequently consulted, that of therapeutic abortion. These operations are being performed more often for psychiatric reasons than ever before. A recent study of California hospitals(1) revealed that over 50% of therapeutic interruptions of pregnancy were accomplished for reasons other than the physical health of the mother. In a recent 10-year period, the percentage of therapeutic abortions performed for psychiatric reasons in New York State rose from 8.2% to 40%(1). Is it possible that instead of being flooded with new insight into the unconscious, doctors are recognizing an easy out when under pressure to stop a pregnancy? Is it possible that the psychiatrist has become the unwitting accomplice?

In all U. S. jurisdictions, it is a crime to induce an abortion unless the case falls within certain exceptions(2). In recent years, it appears that the abortion laws have been interpreted more liberally(3). At the present time, in 31 states, it is a crime to perform a therapeutic abortion unless this operation is necessary to preserve the life

of the mother. For instance, in the State of Michigan,

Any person who shall wilfully administer to any pregnant woman any medicine, drug, substance, or thing whatever, or shall employ any instrument or other means whatever, with intent thereby to procure the miscarriage of any such woman, unless the same shall have been necessary to preserve the life of such woman, shall be guilty of a felony, and in case the death of such pregnant woman be thereby produced, the offense shall be deemed manslaughter. In any prosecution under this section it shall not be necessary for the prosecution to prove that no such necessity existed.

This is spelled out in no uncertain terms in most of the states, although three states make abortion legal when it is done to protect the woman's health as well as to preserve her life.

Since pregnancy is seldom a serious threat to the life of the mother in the face of modern medical management(4), it must follow that many of the recommendations for therapeutic abortion are on other than strictly medical grounds. It must follow, also, that these cases fall into the cloudy area of psychiatric indications for interruption of pregnancy and are, at best, of somewhat dubious legality. It seems possible, too, that in many cases the operations are performed as a result of the elasticity of psychoanalytic considerations or the unfortunate misinterpretation of the individual woman's problems. The question which faces the psychiatrist who bothers to remember the law is "Will the patient commit suicide if we do not go ahead with the abortion?" In most states, the law is specific enough so that we are not allowed to consider whether the pregnancy will bring on mental disease or aggravate pre-existing mental disease. We are also not allowed to consider or make overt statements as to the possible influence of a sick mother upon the child which would be a result of the pregnancy. These are matters

¹ Read at the 118th annual meeting of The American Psychiatric Association, Toronto, Canada, May 7-11, 1962.

about which psychiatrists have very distinct opinions. But these opinions are not provided for in the statutes.

It becomes apparent then that we must state in any recommendation for abortion that the patient will kill herself and we must state this in writing. How sure are we of this prediction? Many psychiatrists have admitted that they do not know of even a single woman who has successfully committed suicide under these conditions. Certainly it is the consensus that these pregnant women very rarely carry out the threat. Some psychiatrists recommend that women who threaten suicide and are obviously going through a severe emotional upset should be hospitalized until the pregnancy is completed and if it makes good sense after delivery, the baby adopted out. It has also been pointed out that psychotherapy has been helpful to patients whose initial visit to the psychiatrist concerns a request for therapeutic abortion(5).

The magnitude of the problem is rapidly increasing. There are thousands of babies who are prevented from entering our society each year by virtue of a so-called therapeutic abortion. How many hundreds of thousands of illegal abortions that are done can only be roughly estimated. These also must be in cases where the women concerned knew or were told that they had no good medical case for interruption of the pregnancy. It has been stated, too, by authorities that a large number of these interruptions are accomplished on married women(2). There are only a small number of pregnancies which really are a result of rape or incest or other unfortunate situations toward which our sympathies cannot help but be extended.

One of the difficulties which a psychiatrist encounters in assessing a case referred to him for recommendations concerning therapeutic abortion is the time element. Most patients come or are sent to the psychiatrist after they have missed at least two periods. The psychiatrist is under great pressure to come up with some kind of an answer within, at best, two or three visits. Arrangements have to be made in a hurry so that the obstetrician, who will perform the procedure, will feel that he is within the acceptable time limit or as close to the

first trimester as is possible. Any examination performed under pressure will run the risk of being incomplete and also of not being objective. The psychiatrist is not only being pressed by the patient, but often every bit as much by the referring physician who has already decided in his own mind that the patient should have a therapeutic abortion but can really find no good medical reason for it. He therefore refers the patient to the psychiatrist in the hope that the psychiatrist will pull the case out of the fire. It is probably true that a great many suicidal intents are grossly exaggerated in order to make the indication not only a legal one, but a justifiable one to the conscience of all concerned. It is also interesting to explore the attitudes of those around the patient as to whether or not someone else is the leading agent for the abortion. Many times, it is the husband who does not want the child or even the mother or mother-in-law who feels, for some reason, that the patient should not have the child. Careful study often reveals the true facts of the situation, namely, that the pregnant woman wants the baby but is fearful of someone else's disapproval. In very rare cases, the psychiatrist, despite his reluctance, might have to admit that it is possible a therapeutic interruption of pregnancy is indicated and that it comes within the meaning of the law. The following case illustrates a possible indication.

The patient was a woman in her early 30's and, at the time of the psychiatric examination, had missed her second period. She had had 5 previous pregnancies; one of the children was drowned at the age of 3 about 4 years before the pregnancy in question. The first 4 of her pregnancies were described as very happy ones and she was completely contented. Her fifth pregnancy was the only one in which she was significantly ill and she said, "I was nauseous from morning to night. After I got a shot, I then couldn't make myself sick, I guess I was making myself sick." The patient was one of those women who insisted that none of the rules of contraception seemed to work for her and, very significantly, she felt that this sixth pregnancy was accomplished without a complete sexual act. The patient developed great resentment for her husband because she felt that this was a sneak attack. This resentment grew from the time of the act of intercourse,

itself, and reached serious proportions by the time she was referred to a psychiatrist.

The patient, on examination, appeared to be seriously depressed and suicidal. She had withdrawn completely from all social life. She had been sleeping most of every day in addition to at night. Her appetite was severely impaired. She was bothered with obsessive ruminations about doing harm to the children she already had. She was bothered by the obsessive impulse to destroy herself while driving the car. Her libidinal interest disappeared completely. It was felt that her suicidal intent was real and that she would not only carry this out but actually might act upon her feelings toward the other children. It appeared, too, that the fifth pregnancy was one in which she strained her defenses to the limit and that this, the sixth pregnancy, would break down those defenses completely.

A therapeutic interruption was recommended and the patient, to the date of this paper, has been described as being very happy by her physician and her relatives. It should be noted, however, that this patient, as most patients who had had therapeutic interruption(6), did not return for follow-up psychotherapy. What remains for her is yet to be seen and it is the author's opinion that the last of this has not been heard and that perhaps during the menopause there will be a flare-up of the old guilt feelings. The author has never seen a patient who has not had guilt feelings about a previous therapeutic abortion or illegal abortion.

It is probable that most psychiatrists, upon examining the above patient, would have agreed on the indications for therapeutic abortion and that the patient fell within the meaning of the law as it has been practiced and interpreted in most jurisdictions. A more interesting case, however, which brings out the need to look for contraindications, and for not accepting the initial statements of the patient is that of the following:

The patient was a 41-year-old woman, who had one child, a son, about 20 years of age. The patient was seen originally in hospital consultation where she already had been given the impression that she had been admitted for therapeutic interruption of pregnancy. The patient went through the usual tearfulness and agitation in describing her depressed feelings and her desire to have this pregnancy inter-

rupted. It was revealed in discussion with her that about 6 months prior to her becoming pregnant, her only son had announced to her that he was a homosexual. This disturbed her greatly, of course, and after 20 years of not becoming pregnant, she suddenly conceived and then, as soon as she knew she was pregnant, began to feel that something would happen to this pregnancy. This opinion was fed by one of her physicians who told her that the pregnancy might not go to term anyway. The patient's sense of inadequacy and guilt concerning what she felt to be a failure in her first child was compounded by the fear of a second error. She therefore stated that she was extremely depressed and did not want to live if she had to go through with this pregnancy. It was quite readily apparent that what this patient was saying was that she feared producing another imperfect child and therefore failing in her role as a woman. It should be remembered that she was nearing the menopause and was quite aware of this. Further investigation revealed that the marriage was not a totally satisfactory one and that here, too, she felt a sense of inadequacy and failure. The psychiatrist refused to go along with the recommendation for therapeutic abortion. The husband phoned the psychiatrist at his office and gave him his opinion in no uncertain terms and told the doctor that he could not understand his reluctance to okay this procedure. He implied that it was not convenient at this time to have a baby. The psychiatrist posed the question, "When is it convenient to have a baby?" At this, the angry husband slammed the phone and ended the conversation. Follow-up of this case revealed that when the woman finally came to term and delivered a normal child, she was extremely happy and pleased and has been ever since. An ironic twist to the whole situation is illustrated by a phone call from the husband to the obstetrician (not the psychiatrist) thanking him for not letting anyone do the abortion.

It seems that a case such as the second one is an excellent example of not taking the patient's statements at face value and of using our knowledge of psychodynamics and of the needs of human beings in coming to decisions of this kind. Despite protests to the contrary, we know that woman's main role here on earth is to conceive, deliver, and raise children. Despite all other sublimated types of activities, this is still their primary role. When this function is interfered with, we see all sorts of emo-

tional disorders and certainly the climax of these disorders is reached at the menopause when women recognize that they no longer can reproduce their kind and interpret the menopause as the end of life rather than the change of life. This is not just textbook theory, as all who practice psychiatry very well know.

It is interesting, too, as we study women who have difficulties during their reproductive years that many, many women who are habitual spontaneous aborters really do not want the children and therefore do cancel themselves out of the reproductive race, so to speak. This is only one example of the influence of the unconscious on the functioning of the female reproductive organs. Another is that of pseudocyesis or false pregnancy in which unconscious factors so influence physiology that even the pregnancy tests may be positive along with amenorrhea, breast tenderness, abdominal enlargement, *etc.* Yet another example is the increase or decrease of sexual desire gauged to coincide with fertile or infertile periods. Some women feel the need for sexual satisfaction only during the menstrual period itself.

In the face of all of this evidence for unconscious influences in women's attitudes toward pregnancy, how can we accept a conscious statement from a woman to the effect that she does not want a certain pregnancy? If we have learned anything in psychiatry, we have learned to respect the unconscious far more than the conscious and we have learned not to take statements at face value.

In the light of the second case, it seems prudent to call attention to the possibility that many women may have had pregnancies interrupted in the past for what appeared to be sound medical reasons, without a psychiatric examination, which might even have offered some possible contraindications to interruption of pregnancy. Certainly, if the life of the woman is in jeopardy due to a medical condition, the author cannot conceive of a psychiatric contraindication, but in so many of our present-day therapeutic abortions, it seems that with a little search we can find many instances of contraindication and can be of greater assistance to our colleagues in this area than

we can in rubber-stamping the first appeals of an angry, frightened patient or her family.

Psychiatrists must not allow their knowledge of psychodynamics to be misused by anyone, including themselves. We have no business allowing our personal feelings about the moral or social or economic position of our patients to influence our decisions concerning therapeutic abortion. There is a statute in most states which spells out what we have to do. If psychiatrists are interested in changing the law, that is up to them, but the author does not believe this is their function. The cases in which unfortunate circumstance has contributed to pregnancy are really few and far between and the vast majority of the requests for therapeutic interruption which are made of a psychiatrist are those of married women in families who can well afford to have children, but who, on first hearing the news of pregnancy, become upset and try to influence medical opinion to interrupt the pregnancy.

As psychiatrists, we must re-examine our position on therapeutic abortion. We must not allow ourselves to be pressured and we must never forget that there are certain fundamental, biological facts which influence the psyche of our patients. We must remember that, in most of the requests which are made to us concerning an interruption of pregnancy, the pregnancy can be carried to term and the patient can be handled either in office treatment or in a hospital until the baby is delivered. The ability of mothers to accept infants after they are born is underrated and underestimated. We also are much too quick to accept trite statements and poorly controlled studies about the influence of so-called sick mothers upon their children.

In summary, the author wishes to call the attention of all psychiatrists to the increasing demands made upon them to make decisions concerning therapeutic abortion. The author asks his colleagues to reconsider their position and, in examining these patients, concern themselves mostly with a search for contraindications rather than for indications to therapeutic interruption of pregnancy. The author further wants to remind the members of the psychiatric pro-

fession that they have no more right to break the law than anyone else in our society and that if they want to change the law, that is their business, but that with only a few exceptions, actually there is good biological, psychological, and moral justification for the law as it stands.

GROSS STRESS REACTION IN COMBAT—A 15-YEAR FOLLOW-UP¹

HERBERT C. ARCHIBALD, M.D., DOROTHY M. LONG, M.A.,
CHRISTINE MILLER, Ph.D.,² AND READ D. TUDDENHAM, Ph.D.³

During World War II and shortly afterwards, many studies were made of combat fatigue or gross stress reaction. In most of these reports, the syndrome was regarded as a transient state. A few investigations have found the syndrome persisting as long as 5 years. It has not been fully recognized that many veterans retain their original symptoms of startle reaction, recurrent nightmares, irritability, and headaches largely unchanged after a decade and a half.

Rather than attempt to review the massive literature on "wartime psychiatry" the reader is referred to a book by that title by Lewis and Engle(1) (review of 1166 articles, 1431 authors). Some hold "combat fatigue" to be a syndrome differentiable from psychoneurosis while others do not. The Gray Manual establishes the following criteria: 1. Unusual stress; 2. Previous normal personality; 3. Reversibility; 4. Possible progress to one of the neurotic reactions; 5. If the reaction persists, this term is to be regarded as a temporary diagnosis to be used only until a more definitive diagnosis is established. However, there is no provision or official name for the continuance of these symptoms.

A study by Dobbs and Wilson(2) illustrates dramatically the persistence of reactions to combat sounds in some veterans. A tape recording of combat sounds was played to three groups of men: men who had never been in combat, men who had been in combat but who showed no signs of psychiatric disability, and combat veterans who had symptoms typical of combat syndrome. Measures of physiological response, such as EEG, pulse and respiration rate, were taken during the playing of the recording. The non-veteran group made mild, orienting responses to the combat sounds.

The psychiatrically well combat veterans had mild to marked physiological and behavioral responses, while the combat syndrome veterans showed such marked behavioral disturbances that it was impossible to record the physiological responses. While the behavior of the combat veterans was described as near-psychotic at this time, the authors report that none of the subjects in their series was so diagnosed.

Inasmuch as stress is defined as one of the key components of the combat reaction it seems appropriate to mention Selye's theory that all disease stems from stress. Not all physicians, psychologists or physiologists agree with this theory but there is general recognition of some link between stress and disease. Selye's now famous G.A.S. concept emphasizes the chemical aspects of the problem and provides that the reaction of the human body to an outside agent is often more important than the agent itself.⁴

The determinants of these reactions may be subtle. William Caudill(3) among others emphasizes the importance of such attitudes toward injury and disease—"attitudes that are deeply imbedded in the personality so that what is considered a slight injury in one culture may be a severe trauma for an individual in another culture." Mead(4) states that in New Guinea attitudes toward cuts and wounds are casual but in Bali where there is an extreme fear of mutilation the practice is to keep cuts and wounds open for several days to prevent early closing and infection. Reaction to the combat situation may vary from group to group. For example many military men have noted the unusual stability of Turkish, Gurka and

¹ Read at the 118th annual meeting of The American Psychiatric Association, Toronto, Canada, May 7-11, 1962.

² Mental Hygiene Clinic, Oakland VA Office.

³ University of California, Berkeley, Calif.

⁴ As Lazarus, *et al.* (U.C.), have shown, the physiological effects of stress may be reduced by changing the meaning of the stressful stimulus to the subject. The physiological effects of a traumatic motion picture on subincision were altered according to whether the sound track accompanying the film was intended to deny, to intellectualize or to maximize the impact of the film.

Scottish Highland troops. We cite this as evidence that socio-cultural factors play an important part in the development of resistance to combat fatigue.

It is interesting to observe that although the combat fatigue syndrome is frequently persistent for many years, a number of veterans delay seeking treatment for their specific symptoms. The Veterans Administration Mental Hygiene Clinic in Los Angeles⁽⁵⁾ studied 200 combat veterans after 5 years and noted "even at this late date (1951) we still encounter fresh cases that have never sought treatment until the present time." Now a decade and a half after the war we can make the same statement. The VA made an extensive "Follow-up Study of War Neuroses" (1000 cases published in 1955). Note that when the study was conducted it was not possible to differentiate the chronic cases.

Chronic "combat fatigue" should not be interpreted as a special case of chronic invalidism. However one common element seen in both instances is the use of symptoms to dominate or punish others, to evade responsibility, to gain attention, to obtain compensation or achieve some other goal. Chronic invalidism has been studied intensively for example at the Langley Porter Clinic from 1944-1947^(6, 7). Their clinical and psychological findings are similar but not the same as those of our experimental group. (We were fortunate in getting an opinion from one of the co-authors of the L.P. study who also went over our data.)

Our clinical impression from interviews and group experience with these men is that in many cases the combat syndrome persists as a chronic state of over-vigilance, one which seriously affects their lives. Needing to avoid noisy and overstimulating situations, worn out by nightmares and sleep difficulties, these veterans often seemed to be more disabled than is generally recognized.

To investigate both the persistence and characteristics of the syndrome, questionnaires concerning health, adjustment, and service experience were sent to 65 veterans who experienced symptoms after an average time of 15 years. A control of 70 non-combat veterans who are or had been patients at the Mental Hygiene Clinic was also studied.

These subjects were selected by a process of restrictive randomization. Fifty-seven combat patients and 48 non-combat patients returned the questionnaires. Minnesota Multiphasic Personality Inventory protocols were also available for most of both groups. It is of interest that while no attempt was made to screen the combat syndrome veterans for schizophrenia, not one carried this diagnosis. Anxiety reaction was their most frequent diagnosis. In the non-combat control group, in sharp contrast, nearly one-half were officially diagnosed schizophrenic. In addition a small group (15) of combat veterans without service connection and who had never requested psychiatric treatment were also given the questionnaire.

The questionnaire and MMPI results⁵ confirm our expectation that in the majority of veterans studied this is a severe and persistent illness.⁶ The combat veterans generally showed more pathology on both the questionnaires and MMPI than did the controls.⁷

The questionnaire contained 64 items of which 24 were symptoms clinically judged to occur frequently in the combat syndrome. The subjects were asked to check whether they had experienced these symptoms in combat (or in the service, in the case of the non-combat controls), on discharge, or at present. A space to check for each time was provided so that a subject could indicate the presence or absence of a symptom at one or more of these times. As expected symptoms highly specific to the combat syndrome were checked far more often by the combat group, *e.g.*, combat dreams and startle re-

⁵ We wish to credit Harrison Gough, Ph.D., University of California, for his assistance in the analysis and formulation of part of our data.

⁶ The majority of veterans in this series receive some compensation from the government—some receive none—many receive compensation for gunshot wound, not psychoneurosis. Concentration camp syndrome, as presented by Bettelheim, Eitinger⁽⁸⁾, and others is similar to gross stress reaction in combat. A research team in Norway found that 96% of persons investigated fairly recently continued to experience symptoms resulting from their stay in the concentration camps. Note that most of these civilians have received no monetary compensation.

⁷ Fourteen combat syndrome wives showed the reverse compared to 54 wives of non-combat veterans.

actions. However symptoms characteristic of the combat syndrome, but less specific to it, such as dizziness, blackouts, sweaty hands, and jumpiness were also much more often checked by the combat group.

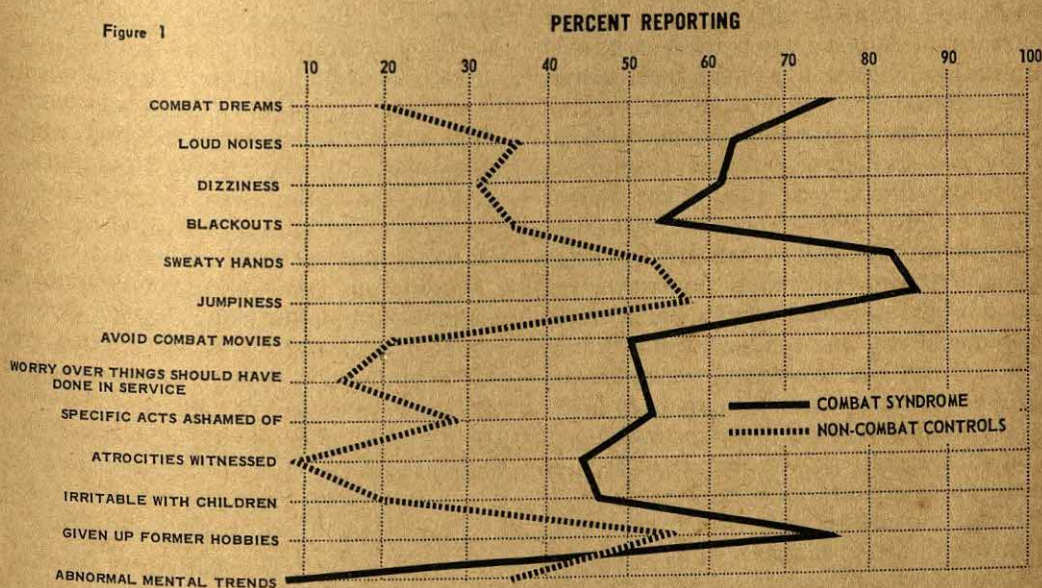

The picture of the syndrome growing out of the questionnaire is one of tension, irritability, depression, diffuse anxiety symptoms, headaches (70%), insomnia and nightmares. The combat veteran typically avoids all situations where he may be subject to sudden loud noises and reminders of combat, such as combat movies and TV. He has often given up hunting because he does not want to use a gun. In comparison with the non-combat controls, he is more laden with guilt and concern over hurting others. He tends to internalize his problems and tries to avoid outward expression of his feelings. Thirteen of the most important symptom differences have been selected for presentation in Figure 1.

be of the "stable unsatisfactory" type.

With regard to persistence of symptoms over time we found that all but 3 of the 24 symptoms were reported more frequently in the present than in combat or on discharge. Those less frequent at present are combat dreams, nail biting, and excessive use of alcohol. We noted the same tendency to report more symptoms currently than in the past also in the non-combat controls, perhaps reflecting a tendency for chronically ill people to complain of present rather than past symptoms or perhaps a tendency to convey the idea that they are not getting any better.

In the foregoing discussion we have not mentioned the results on the questionnaires from the small group of combat veterans who have never been psychiatrically ill. In marked contrast to the clinic groups, these men reported very few symptoms and little avoidance of situations similar to combat.

Figure 1

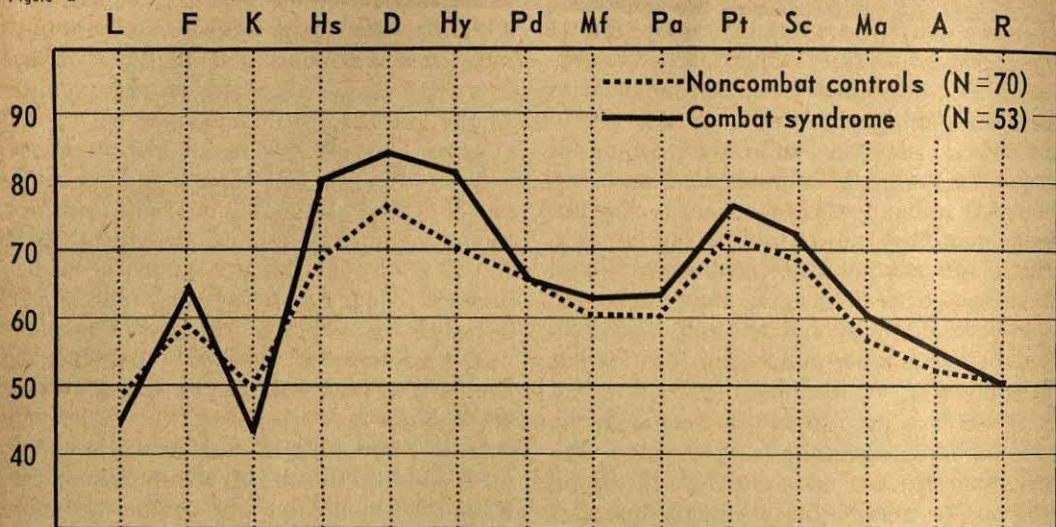

DIFFERENCES SIGNIFICANT AT THE .05 LEVEL OF PROBABILITY.

Over half of the combat group had been wounded in action compared with none of the controls. Eighty-two percent of these men report that their psychological symptoms have interfered with their abilities to provide for their families in contrast to 71% of the non-combat controls. More combat veterans are married than the non-combat controls; however these marriages tend to

Figure 2 will show that the mean MMPI profile of the combat group is generally more elevated than that of the non-combat controls. The only scale having a difference which reaches statistical significance is that of hypochondriasis, which is higher for the combat group at the .01 level of probability. (An earlier study at Langley Porter Clinic on acute cases of head injury showed that

Figure 2

patients who would become chronic had elevations on the hypochondriasis and hysteria scales.) An item analysis of all the MMPI items indicated that except for nightmares and sleeping difficulties the combat veterans as a group do not report particular physical symptoms but rather generalized tension and discomfort. Like the L.P.C. our experimental group also tended to be of lower middle class socio-economically. On the MMPI significantly more of the combat group reported that they had been slow learners in school and expressed naive ideas about religion. We therefore compared the educational and occupational level of the combat and non-combat control groups by means of the Warner rating scale and did find that our combat group were lower in both educational and occupational level than the controls. We wonder if slow learners may be slow unlearners.

Another characteristic of the combat syndrome group is that they lost a parent before the age of 14 more often than the general population (9). Classification according to the age of bereavement revealed the same incidence in the first 4 years of life as the next 8 years combined—a sharp reversal of the increasing incidence of parental bereavement with age in the general population. Our combat group resembles our total clinic population in both a higher rate of parental bereavement in childhood and a high rate of such loss in infancy compared to later childhood. This finding along with

their lower socio-economic status seems to be evidence of a history of deprivation which may have been predisposing to chronic illness. Despite the generally higher elevation of the combat veterans' profile, the item analysis findings are consistent with the official diagnoses in showing that these men do not have psychotic trends. (Only 4 combat veterans reported abnormal mental trends on the MMPI. These did not occur in the actual area of combat in 2 cases, the other 2 experienced loss of consciousness due to shell explosion.)

Implications for therapy. A new therapeutic technique is being instigated in a group of men with the combat syndrome. Our hypothesis is simple: combat was experienced in a group situation therefore it can best be abreacted in a group setting. Verbal reports of these men emphasize the intense symbiotic relationships of the combat unit, which when dissolved leave a feeling of lack of purpose. For these men we deliberately recreate a "band of brothers" and foster the abreaction they have hitherto assiduously avoided.

The great war has brought significant changes in our national life. The impact of this devastation has not become fully realized after a decade and a half. This is especially true for the members of our combat group which have spent over 100 hours together. We do not apologize for mental indigestion and lack of sleep following the two-hour sessions. These men have no-

where else to speak out. They have all changed under the guns. But their life of danger was exciting. There is a paradox here—after they looked death squarely in the face one would think that life would thereafter take on new meaning—for this group the reverse has occurred. These particular combat veterans cannot blot out their burdensome bloody memories. Of course the man in the street says "Forget it—the war was over 17 years ago" and therapists have said the same, forgetting that Freud taught us that the unconscious is timeless.

At present the sale of pocketbooks on combat is tremendous and combat and naked aggression are seen on every TV screen. Our group however has to fight off the tendency to turn the dial—they have had enough—a belly full—but they must have more (perhaps to satisfy some primitive predatory impulse which once ignited cannot easily be extinguished).

There were 1000 different wars. It was not the same for the group member who went down with the Monson as it was for another member who watched the same battle from the beach. The latter did not then know that in another war he would be defending the crucial ridge where the Communists attacked unexpectedly. He did not know then that he would become a double amputee and receive the Congressional Medal of Honor. And he did not know that the medal would at times become a millstone around his neck.

These particular men were loners. In the group they see themselves reflected in the other—and seek to find meaning in the gigantic useless slaughter which they physically survived. Every unexpected sound causes a perceptible jerk. Who will understand that—after 17 years? It was yesterday in the unconscious. These men have a message but who will listen? They have experienced Sherman's hell—they belonged to the most interdependent group in the world. But when a finger of this symbiotic group is yanked off the hand there is no attempt even to contact the others after the war. The group has raised the questions "Who are we? How did we get this way? And where do we go from here?" The degree

of symbiosis of the combat group has been only recently recognized in the literature but it has been known for several hundred years :

We few, we happy few
We band of brothers;
For he today that sheds his blood with me
Shall be my brother

—Henry V

SUMMARY

While there are similarities between the combat patients and the non-combat controls, a clear-cut picture emerges of the combat veteran syndrome with a severely disabling condition involving startle reactions, sleep difficulties, dizziness, black-outs, avoidance of activities similar to combat experience, and internalization of feelings. He is not however psychotic.

The achievements of the medical and allied professions especially in dealing with the acute combat cases have been valuable but less and less interest is being shown to this particular group of veterans. In many hospitals and clinics there is no official record kept as to whether a patient was ever in combat. It is suggested that if we are to continue to study this group of patients we must at least keep track of them. Particularly with the recent emphasis on "here and now" in psychotherapy a combat veteran's tendency to avoid discussing his traumatic combat experiences may easily create a tacit agreement between the therapist and the veteran to avoid the subject. We suggest that a continuing and broadening attack on the psychological aspects of these problems is indicated. Such a study will help to clarify our concept of psychoneurosis in general and contribute to the maintenance and improvement of these men.

MIND TAPPING : PSYCHIATRIC SUBVERSION OF CONSTITUTIONAL RIGHTS

THOMAS S. SZASZ, M.D.¹

The right to a public trial and to decent limits on methods permitted the prosecution for incriminating the accused are among the most important features of a free society. The more these liberties are compromised, the more tyrannical is the government's hold over the people.

The expanding use of psychiatric interventions in the enforcement of the criminal law has, in my opinion, steadily diminished our constitutional liberties. The recent practice of pretrial psychiatric examination of defendants, on the order of the court and against the wishes of the accused, promises to effectively nullify some of our most important constitutional rights—namely, the right to a speedy trial and the right, in the words of Louis D. Brandeis, “to be let alone.”

II

The Sixth Amendment to the Constitution guarantees that :

In all criminal prosecutions, the accused shall enjoy the right to a speedy and public trial, by an impartial jury of the State and district wherein the crime shall have been committed, which district shall have been previously ascertained by law, and to be informed of the nature and cause of the accusation; to be confronted with the witnesses against him; to have compulsory process for obtaining witnesses in his favor, and to have the Assistance of Counsel for his defence.

The Sixth Amendment does not say that this right is contingent on the ability of the accused to prove his sanity to the satisfaction of government psychiatrists.

The right to be let alone (more specifically, the privilege against self-incrimination) has received extensive judicial consideration—for example, in connection with wire tapping as a method of securing evidence for use in criminal trials. The majority of the Supreme Court judges—wrote Justice Douglas—have found “that wire tap-

ping violated the command of the Fourth Amendment against unreasonable searches and seizures, and infringed on the guaranty of the Fifth Amendment that no one person shall be compelled to be a witness against himself.” Chief Justice Oliver Wendell Holmes called wire tapping a “dirty business.” Associate Justice Louis D. Brandeis held that the Fourth and Fifth Amendments conferred upon the citizen, as against the government, “the right to be let alone—the most comprehensive of rights and the right most valued by civilized men. Wire tapping was the most oppressive intrusion into the right of privacy that man had yet invented.” Evidently, Brandeis did not anticipate involuntary pretrial psychiatric examination. This, I submit, is an even more insidious invasion of privacy, and an even greater violation of the privilege against self-incrimination, than wire tapping.

It may be objected that mind tapping, as against wire tapping, is intended for the defendant's benefit, and hence, in the final analysis, is not injurious to his “best interests.” Let us see if this is so.

III

Mental illness or incompetency, of sufficient severity, has, for a long time, constituted an excusing condition in the Anglo-American criminal law. Since mental illness is considered to be an excusing (or sometimes a mitigating) condition, it logically falls upon the shoulders of the accused, or his counsel, to introduce this issue into the criminal proceeding. In other words, just as the defendant has the right to plead either innocent or guilty, so he has the further right to plead insanity. He also has the right to plead that, because of the state of his physical or mental health, he can not effectively assist in his own defense, and hence ought not to be tried. This plea implies that the accused will submit to treatment so that, as soon as he is restored to health, he can be tried.

Progressive psychiatrization of the Ameri-

¹ Professor of Psychiatry, State University of New York, Upstate Medical Center, Syracuse, N. Y.

can criminal law in recent decades has introduced a new wrinkle into this traditional scheme. In the first place, mental illness is no longer considered to be merely a "defense." Instead, it is considered to be a disease like any other disease—a scientific "fact" which is alleged to be "objectively verifiable" by psychiatric experts. Second, psychiatrists have shown great alacrity at meting out life sentences in psychiatric institutions to people whom they consider deserving of this fate.

These two developments have made the issue of the defendant's possible insanity of considerable interest and attractiveness not only to his defense counsel, but also to the prosecution and the judge. For the prosecution, establishing the defendant's insanity, instead of his guilt, may become an easy method of securing "conviction" and "imprisonment"; the defendant will be incarcerated in a psychiatric institution for an indefinite period—a sentence at least as severe and probably more so than would result from conviction and sentencing to a penitentiary. To the judge, too, establishing the defendant's incapacity to stand trial may be tempting; it will save him the effort of conducting a trial that may be filled with distressing emotional and moral conflicts and dilemmas. Both he and the jury will be spared a taxing existential encounter, if only the defendant could be shown to be crazy. These are only a few of the more obvious incentives and seductions that may motivate men to subvert the rights guaranteed by the Constitution and the Bill of Rights. There are others.

IV

There is an important difference, however, between wire tapping and mind tapping. Wire tapping can be carried out without the suspect's awareness, and hence also without his consent and cooperation. In contrast, mind tapping—for that is what involuntary psychiatric examination really is—requires a measure of cooperation on the part of the subject. The question arises, what happens if the defendant refuses to submit to pretrial psychiatric examination?

As a rule, pretrial psychiatric examination is a consequence of a plea of insanity on the part of the defendant. In some of these

cases, the defendant submits willingly to examination by his own psychiatrist, that is, by the psychiatrist retained by the defense counsel, but refuses to be examined by the psychiatrist retained by the prosecution. In the face of this dilemma, the courts and legal scholars have held, first, that a person's unwillingness to participate in a psychiatric interview is itself *prima facie* evidence of mental illness. The defendant may thus be committed to a mental hospital, where he will stay until he cooperates with the psychiatrists, and perhaps longer. Second, they have suggested that when a defendant pleads insanity, and yet refuses to submit to a pretrial examination at the hands of psychiatrists appointed by the court or by the prosecution, his refusal ought to be interpreted to mean that he is competent to stand trial.

Suppose, however, that the issue of insanity is raised not by the defendant (or his counsel), but by the court (or the prosecution). Suppose, further, that the defendant refuses to submit to pretrial psychiatric examination, and demands to be tried. What would happen in such an instance? How would the criminal action against the defendant proceed?

This is an exquisitely significant dilemma. If a defendant had the good sense to refuse to submit to a court-ordered psychiatric examination—for, obviously, today he has nothing to gain, and everything to lose, by submitting to it—he would force the hands of the judge and the prosecutor. Indeed, we might look on such refusal as similar to a well-designed experiment in physics. From its outcome, we could draw far-reaching inferences about the particular social processes that we are observing, just as a good experiment in physics allows us to draw inferences about the physical processes that are being investigated.

V

Like all crucial experiments, this one too seems to be carried out only very rarely. In most cases, the defendant is an indigent person, who, unassisted, is probably unable to understand the complexities of the situation; and he is usually poorly represented by court-appointed defense counsel. There may be other reasons as well why this

dilemma has thus far been not more sharply etched.

Recently, however, two clear-cut answers, each from a different source, have been supplied. The first comes from Stephen S. Chandler, Chief Judge of the United States District Court for the District of Oklahoma. Judge Chandler presented his views on law and psychiatry before the Hearing of the Senate Subcommittee on the *Constitutional Rights of the Mentally Ill*, in Washington, D. C., on March 30, 1961. In reply to a question about what he would do if he suspected that a defendant was mentally ill, Judge Chandler stated that he would send the defendant to the medical center for federal prisoners, at Springfield, Mo., for psychiatric examination. He enlarged on this :

I have sent defendants to Mr. Bennett's [James V. Bennett, Director, U. S. Bureau of Prisons] Springfield institution, and I find that I do not know where the money comes from to pay these psychiatrists but surely it is provided in 4244, is it—I have not read it in many years—but I just appoint them. The Department of Justice pays the psychiatrist, and they have never raised any question to me and I appoint good ones, and then see to it that the psychiatrist does not get any information—that *the Government does not try to influence him*. I ask him to take the case and study it and give me a report that I can depend on.

I do not appoint a psychiatrist in whom I do not have the utmost confidence as to his ability and integrity.

If there are any others, I do not know. I think it is important that the judge have confidence in any doctor whom he appoints.

I might say this : In this work we have lots of problems. Sometimes Government officials do not cooperate fully. But I want to say this about the witness just before me, Mr. Bennett, if a judge cares enough to go to the trouble to take matters up with Mr. Bennett, he will help you work matters out to the extent of his facilities. He does not have enough doctors, he does not have enough facilities, it is pitiful, and I would say to this committee that he is a great and good man. I have learned that in 18 years of contact with him as an official, and I would consider very seriously any of Mr. Bennett's recommendations, because I think he knows better than anyone.

I think he has no ax to grind with anybody except to do a fine job and he looks at it as some Government officials do not, from the

standpoint of the defendant as, of course, the judge should. [Italics added; p. 248.]

It should be noted that Judge Chandler tried to define this procedure as being for the welfare of the defendant.

Miss Elyce H. Zenoff, Counsel for the Subcommittee, then asked the question that constitutes the "crucial experiment" :

Miss Zenoff : "What do you do, Judge Chandler, if the defendant himself insists that he is not mentally ill and you think he is ?"

Judge Chandler : "If there is a question about it, of course, I appoint a psychiatrist, and then if the doctor says there is a question about it, I send him to Springfield to get a report from there, and the only trouble with that is it is as good an institution as Mr. Bennett can make it with the help he has, but he should have a great many more psychologists and psychiatrists there to help him, because at the present time I am informed, that *they can only consult with the man you send there about once a month* ; and as to the therapy that he gets and what they know about him, they do not have the staff to make the report that they would like to make, and we would like to have.

"What they do, they do very conscientiously."

Miss Zenoff : "What I mean, Judge Chandler, is if they report back to you that the man is mentally ill, and he says, I want to be tried ; in other words, I am not mentally ill, what do you do then ?"

Judge Chandler : "Yes. If they find that he is not able to stand trial because of his mental illness, why, I look into it and have a hearing, and if that is right, *he is left there until such time as they report that he is able to stand trial*. But at any moment that it came to me that *someone* thought he was able to stand trial, why I would see to it that an immediate hearing was had to determine that question." [Italics added; p. 248.]

The defendant's own plea to be allowed to stand trial would thus be overruled solely on the basis of the opinion of government psychiatrists. Note, further, that Judge Chandler went so far as to add that should it come to his attention that "someone thought he [the defendant] was able to stand trial," he would hold a hearing "to determine that question." Evidently, the defendant is not included among the people grouped under the heading "someone" for his protestations of sanity have al-

ready been ruled out of court by Judge Chandler.

But it is precisely to the accused—not to his wife or father or friend or attorney—that the Sixth Amendment guarantees the right to be tried!

Recently, in the prosecution of Mr. Bernard Brous, our crucial experiment was carried out with a somewhat different result. As will be recalled, Mr. Brous is one of the men charged with blowing up two telephone microwave relay towers in the Nevada-Utah desert, in May 1961. At the time of his arrest, he was quoted as saying that he committed these acts in protest against certain government policies. Thus, the unusual criminal acts presumably were intended to call attention to himself and his views.

According to an Associated Press news dispatch, dated August 14, 1961, printed in *The New York Times*, August 16, 1961, this is what happened to Mr. Brous:

The Government asked Federal Judge John Ross Monday to find Bernard Brous in contempt for refusing to undergo court-ordered mental examinations . . .

Judge Ross ordered psychiatric examinations Aug. 3.

United States Attorney Howard Babcock presented an affidavit by a psychiatrist, Dr. Otto Gericke, Superintendent of the Patton, Calif., State Hospital, who said Brous twice had refused to submit to tests.

The cat is now out of the bag. If the pretrial psychiatric examination is really for the defendant's benefit, why should he be punished for refusing to submit to it? If, on the other hand, it is not for his benefit, then it must be for the benefit of either the judge or the prosecution. In this case, mind tapping would be a clear violation of constitutional rights. Lastly, the prosecution's demand for finding Brous in contempt of court betrays bad faith and unfairness on the part of either the prosecutor or the judge, or both, for it shows readiness to "try" the defendant for his behavior in the court room at the very moment when the court shows itself reluctant to try him for his behavior in the Nevada desert.

Every reader, of course, is free to draw

his own conclusions from Judge Chandler's views and from the action of the government in the Brous case. I should like to re-emphasize two points.

In the procedure advocated by Judge Chandler, the mere suspicion of mental illness results in the defendant's loss of the right to be tried. In the Brous case, refusal to submit to court-ordered psychiatric examination is not considered an intelligent defense of one's constitutional rights, but instead is regarded as a fresh offense. Thus, the defendant who protests against involuntary mind tapping, like the "Fifth Amendment Communist" of the McCarthy era, is not supported by the court in his efforts to avail himself of his constitutional rights. Instead, he is attacked for his very self-defense!

VI

Reflecting on this problem, we should not forget the values inherent in the right to be tried, in *public* and by one's *peers*, and also the values inherent in the right to go to jail, instead of being subjected to unwanted psychiatric "treatments." In a jail, a person is "let alone"; in a mental hospital he may not be. A prisoner will be released after he completes his sentence, and possibly before. A mental patient may be required to undergo a change in his "inner personality"—a change that may be induced by measures far more brutal and intrusive than anything permitted in a jail—before the psychiatric authorities let him go. And they may never let him go. Commitment, unlike a sentence, is for an indefinite period.

How different the world might be today if only a handful of people had been sent away for psychiatric "treatments," instead of being tried and sent to jail. Gandhi, Nehru, Sukarno, Castro, Hitler—and of course many others, for example, the "freedom riders" in the South—have been sentenced to terms in prison. Surely, the social *status quo* could have been better preserved by finding each one of these men mentally ill and by subjecting them to enough electric shock treatments to quell their aspirations.

If this is not the sort of tyranny against which the Constitution was intended to protect us, what is?

VII

My argument rests. Some may object. After all—they may reply—psychiatrists are honest men. They would not claim that a person was mentally ill if they did not believe it was true. I have no intention of impugning anyone's honesty. But honesty is not the issue. The issues are mental illness and the right to be tried.

What constitutes mental illness is conveniently undefined. Its presence is ascertained by reference to the judgment of experts, in this case, psychiatrists. In this respect, mental illness is like witchcraft, which was also never clearly defined, but which experts had little difficulty diagnosing.

Given these circumstances, I submit that government psychiatrists (or so-called for-

ensic psychiatrists, generally)—like ecclesiastic witchhunters—will easily find large numbers of mentally sick people. This will be especially true whenever the "right" sorts of persons prefer the "charge" of insanity. If this is doubted, we should only ask ourselves how long the witchhunter who never found witches would have lasted in his job? Similarly, how long would a court retain a psychiatrist who found most defendants fit to stand trial, and who would never interfere on psychiatric grounds with the trial of a defendant who wanted to be tried. Finally, would such a psychiatrist be as popular as those of his colleagues who find the defendant incompetent to stand trial in virtually every case in which this issue is raised by an important personage, whether judge, defense counsel, or prosecutor?

BEHIND THE SCENES IN COMMUNITY MENTAL HEALTH¹

HERBERT DORKEN, Ph.D.²

The World Health Organization's philosophy is that health should be regarded not just as the absence of disease, but as a positive state of well-being. This far-reaching concept was reflected in the activities and concerns of World Mental Health Year; it is reflected in the studies of the Joint Commission on Mental Illness and Health. Jahoda's review(11) of the *Current Concepts of Positive Mental Health* (one Commission report) points to the broad social orientation that is implicit in these new community mental health programs. Here then is the ultimate goal: the conservation, development and full utilization of human resources.

Cast in these terms, the concept of community services emerges and is in line with public health philosophy. Public health, however, is concerned with the prevention of disease and the promotion of health through work primarily with the community rather than with the individual(18). For mental health personnel, this is in essence a new type of social contract involving the added dimensions of sound public relations and employer-employee accountability, since beyond the traditional diagnostic and treatment (clinical) services there lies a whole gamut of community services: consultation to agencies and professions in the community, collaboration and cooperation with them in the development of services, coordination and integration of related services, participation in community planning, the provision of public and professional education, and emphasis on survey, evaluation and research(5). I might add that we especially need to learn more about using and developing the strengths and abilities of men, instead of

eternally studying their weaknesses and sicknesses. A concern with human assets is more in keeping with positive mental health than endless dwelling on the ramifications of psychopathology. With this comment on the direction of much of our current research, I will return to the theme.

PUBLIC SUPPORT

The involvement of society facilitates, indeed, renders possible, service to it. The mental health associations often provide the medium through which public interest may become manifest. Certainly, in Minnesota, we owe much of our progress to the active support of the Minnesota Association for Mental Health. From the inception, when they supported the legislation under which we now operate, to their consistent and persistent interpretation to the public of our financial needs and present and projected services, they have been a moving force. At critical stages in program development it is advisable to involve key professional groups such as the state psychiatric, psychological, social work and medical associations in planning. They are often able to provide constructive guidance, and potential differences and difficulties may be resolved beforehand. Public support then and, of course, professional participation are the cornerstones of a community mental health program. But both the social and the professional aspects are influenced by factors, though known, which we tend to overlook—factors that operate, so to speak, behind the scenes.

SOCIAL IMPACT AND CHANGE

The increasing scope and expanding knowledge of mental health concerns has led to increasing specialization and to a process of differentiation and upgrading(14). Also, the complex cluster of interlocking bodies of knowledge and the growth of specialization is such that collaboration among a number of disciplines is now required. Current trends appear likely to continue. This increasing emphasis on the

¹ Presented in part, Third World Congress of Psychiatry, Montreal, Canada, 1961 and expanded following tri-state review of eastern community mental health services, Mental Health Project Grant OM-646.

² Formerly, Director, Community Mental Health Services, Minnesota; presently, Deputy Director, Liaison and Prevention, Dept. of Mental Hygiene, Sacramento, Calif.

psychological, social and occupational factors in mental health suggests an expanding and more significant role for the behavioral sciences.

In terms of the American value system, the capacity of the individual to achieve is one of the most fundamental conditions of the good society. Since mental health is one of the foundations of this capacity, its importance takes on a broader meaning. The gathering impetus of the mental health movement shows plainly that it is a developing social force(16). People consider now that they have a right to a reasonable adjustment. They believe that science and the mental health professions can improve their lot. As a result, communities are becoming increasingly active in demanding and in organizing comprehensive mental health programs.

The needs, resources and social groups in a society are in continuous change. This should be reflected in appropriate program changes or there will be the equivalent of a cultural lag. Unfortunately, there is a tendency for professional roles and services to become stereotyped, if not biased(19). Such professional expectancy leads to static patterns and narrow definitions which stifle creativity. A spirit of restlessness must be induced or maintained, for if progress is our aim, then programs must have a "growing edge" in search of new ideas, improved services and better utilization of the full range of community resources.

We are over-prone to consider mental disorder as the prime factor leading to treatment or demand for mental health service, when, in many instances, the degree of community tolerance will provide the basic impetus to seek professional assistance. There is a distinct relationship between social conditions and the ways in which mental disorder is dealt with by the community (6). Mental illness in social terms is behavior deviant from the norm. Expectations within a particular society and the context of the action are factors bearing heavily on local attitude and determination which in turn are related to need, demand and utilization of service, and, ultimately, serve to shape professional services and practice.

Taking the larger picture into considera-

tion brings the total range of disordered behavior into focus. These ramifications are an integral part of society. To the extent they are overlooked, we fail to provide an effective community service. The professional staff, then, might be viewed as change-agents who would attempt to induce constructive social change in the community. We have only begun to explore the potential mental health effects of adverse social conditions. Certainly, failures in adjustment, shifts in values and cultural patterns, and social dysfunction, as well as disharmony within families, are hardly individual matters. The findings of research on group dynamics and communications, then, are quite germane and should become a part of our practice and program planning.

PREVALENCE-INCIDENCE

Without proper survey and data we do not know the nature and extent of actual problems requiring attention; we do not know whether we need a particular mental health service. Certainly, it is not another "industry" to be attracted to town. cursory surveys may magnify the problem by use of prevalence statistics, but the number of active cases is not an appropriate basis for making probability statements for which incidence rates—the number of new cases during a specified interval—are essential, though seldom obtained(10). Each community has its backlog of cases with protracted mental disorder. If this backlog could be worked through at the case level by effective management, treatment, placement or referral, the mental health center would begin to deal with the natural base rate or incidence of mental disorder in the community rather than its prevalence.

Related is the need for continuous program analysis; failure to evaluate past work and future needs critically results in errors and mistakes never becoming known and, presumably, never corrected. Stock taking is essential, not only of the mental health services but of the major social, economic and demographic community data as well; this is in constant change, the urban population drift being merely one index. The everyday operations and concerns of community services are rife with intriguing and

very practical research problems. Here again, pathetically little is being done.

FAMILY THERAPY-AGENCY COMPLEX

Without trying to minimize the extent of the problem, several studies have shown (7) that a relatively small number of families and individuals keep producing the bulk of agency activity (2). This activity by many agencies with the same family, the multi-problem family, creates the impression of vast numbers when actually it is a symptom of uncoordinated activity, often with different facets of the same core problem. The need for an integrated system of discovery, identification, ambulatory treatment, nursing home and hospital care is pressing. That the multi-problem families involve a small segment of the population suggests that it may be more feasible than many of us think to serve the total community, as problems of the large majority may be more amenable to assistance.

The history of health and welfare service development is replete with examples of rivalry, competition, duplication and fragmentation. For sake of clarity perhaps in the mental health field, attention has been focused mainly on the individual. Yet, in our society, the family is the basic social unit. Each family will have its unique patterns of interaction. Evaluation and treatment, if geared to this natural social unit, would not only avoid many of the handicaps of partial or incomplete service, it would facilitate the resolution of the emotional and social problems not just of the patient, but of other family members, and lead to a realignment of family patterns of interaction, thereby facilitating progressively more favorable adjustment.

If service is to be comprehensive it should be available to all within the community; all ages, all relevant disorders of behavior, all agencies and professions. Fragmented service may be easier to initiate (e.g., for children, the retarded) but more difficult to sustain, since it depends more on a specific interest group than on community wide support. In order to gain the stability that comes from community wide support and involvement, the service must be widely available and not the agent of any one group or profession (related service) or

even identified in the public mind as such (restricted service). The location of the community mental health center often has a significant bearing here in shaping the public image of its service. Location in a welfare building, school or hospital, to illustrate, generally creates the assumption, respectively, of service for the indigent, the children, the sick—thus impairing a community wide orientation and service.

CENTER-HOSPITAL RELATIONSHIP

Considerable attention is paid to the coordination between mental health centers and state hospitals, particularly in regard to aftercare. In some states this may be their major function. By contrast it is seldom thought that centers may be dealing with essentially different segments of the population. In Minnesota, but 5% to 8% of center admissions are referrals from state hospitals, while conversely, termination by referral to hospital varies from 6% to 10% of cases closed. The trend, if any, is for centers to refer progressively fewer patients to state hospitals. Our recent statistics would indicate that the centers deal with a population largely different from that of the mental hospitals and that they are reaching a large segment of the community having emotional, mental and social disorders, and, it may be assumed, not previously reached.

The progressive emphasis on community services notwithstanding, there has been a sharp rise in the diagnostic and treatment services provided by the centers. The number of new cases accepted in 1959-60 was more than double the pace of the previous year (22) while 1960-61 showed a 64% gain over 1959-60 with but one new center and a 25% increase in staff. The total of new admissions (4,731, and now projected at over 5,200) has risen to more than double the first admissions (2,188) of mentally ill to all state hospitals (7 hospitals, 9,600 beds) and is substantially above total admissions (3,142) and even hospital admissions plus return from provisional discharge (3,975). This is roughly an average rate of 28 new admissions per center per month, carried by a total of only 43 professional staff (latterly) at 14 centers, devoting but an average of 48% of professional time to clinical services.

PREVENTION-CONTROL

Much lip-service is given to the need for a preventive approach to mental illness, for programs of public and professional education, for coordination and consultation, for the concentrated development of additional community resources, and for research; yet, when any mental health center is established, there is often an overwhelming demand for clinical services which may become so exclusive that program control and direction are basically lost.

In developing the service, at the outset, in response to community need, there is usually the hope that it will help to control the problem and have a preventive impact. But this development is open-ended, a progressively increasing amount of service is provided, yet responsibility for its effectiveness is basically evaded. Service does not, by itself, lead to prevention or establish control, is usually without focus and direction and, most important, is without responsibility for results(3). Specifically, what are the problems and their proportions? How are these conditions modified, controlled or improved? It is essential that the critical factors be isolated in order to enhance the impact of our services and techniques.

Then there is the concept of accountability, a most challenging proposal(17), though, generally, a most unwelcome and unpopular notion among clinicians who are prone to be ego oriented rather than task oriented. A statement of activities is not synonymous with accountability. Yet, without defined goals and accountability, control and direction are lost and prevention fades into obscurity. Moreover, and this is seldom appreciated in the field, to the public official accountability is a reality of everyday, whether knowledge is incomplete, adequate or even accurate; answers, often critical, must be given.

We have only begun to consider the potential of a reorientation of total community health and welfare services leading to a solution of the community problems stemming from disordered behavior. Rather than deal with symptoms of behavior, attention must be focused on the pathological processes giving rise to social disorder. This need for service has been separately in-

terpreted by each agency. Finally, the problems related to criminal and antisocial activity accounts for two-thirds of the annual incidence of disordered behavior, yet communities have generally ignored this area in planning services. Buell's(3) findings in the Community Research Associates studies hold much promise and have tremendous implications.

UNFOUNDED CLAIMS

At times, some of us venture beyond the realm of our skills and a "halo effect" may mask our inadequacies. At other times, overextended claims may be made for certain services, and this can prove awkward later on, especially if no provision is made for the demonstration of results.

All too often, in the mental health field, our procedures are founded on unconfirmed hypotheses rather than valid explanations. Therapeutic zeal may militate against scientific determination, particularly in regard to the efficacy of psychological forms of treatment. Despite the high fashion and great investment of time over years in long-term, intensive, dynamic psychotherapy, there is no evidence that it is superior to less rigorous methods, in fact it would seem that methodology is being preserved for its own sake(2, 19). It is, of course, asking a great deal of many psychotherapists and analysts to cooperate in trying to find out whether they may be deceiving themselves as to the usefulness of their life's work(12). Rogers(15) and others, however, have made some definite progress in their attempts to isolate (or insulate?) the factors necessary for therapeutic personality change.

LOCATION-DISTANCE

Service, to be provided, must be available. Logical planning would fix location at the hub of the professional and medical community for the area and at the center of trade and transportation. Such logical planning (sociological) may be set aside by local prejudice, political considerations and chamber of commerce activity. Witness state and provincial hospital programs, the majority of such hospitals in North America being located in towns of under 10,000 population(22), in the shadow of isolation, with resultant removal from the sphere of

related services essential to programming.

The growth factor of organizations perhaps has led to the development of over-large mental health services responsible for vast geographical areas, the patient alas fading into insignificance. The lesson for future community mental health planning is that small centers, well disbursed, will render better service—a service more dependent on individual skill than on organizational size or structure. The natural geographical boundaries will vary from place to place. In Minnesota, with its relatively low population density, a radius of 60 miles was found to be the effective limit(8), about an hour's drive by car. Adequate coverage at greater distance could only be achieved by regular staff travel into the outlying area.

Distance, while it has a very direct relation to frequency or use of clinical service (diagnosis and treatment), also has a qualitative effect, the greater the distance, the more serious the disorder, and the more inappropriate it becomes for an outpatient service. There is a significant relationship between the increase in distance and the severity or flagrancy of the disorder which compels people to overcome this barrier. Outpatient services are more frequently unsuitable and follow-up more impractical. If anything, distance causes an even greater impairment of community services (consultation, in-service training, community planning, coordination)—the services essential to maintenance of a public health orientation in program—the services more closely involved with social structure.

FINANCING

Stable and sufficient financing is basic to the proper development of a full service and the initial budget is critical. If realistic provision is not made at the outset for the predictable complement of professional and clerical personnel at regionally competitive salaries and with necessary equipment and supplies, then neither personnel nor facilities will be sufficient and an overburdened agency will be repeatedly turning to its backers, hat in hand, for one item or another—a process guaranteed to antagonize and discourage staff, board and local government. By contrast, a complete initial

budget facilitates recruitment to complement and purchase of all necessary equipment (budgeted funds not expended may simply be returned to source or placed in a special fund for future contingency). Then, in the second and third years, the funds previously necessary for equipment, say \$4,000 (likewise fee revenues), are available as a cushion to accommodate salary increments with the result that the cost to the sponsors remains stable for at least three years while the center establishes and proves itself. At this point, the likely attitude, on returning to the sponsors—if necessary—seeking a moderate adjustment of budget, will be one of reasonable expectation and efficient management.

A positive relationship exists between community visibility, knowledge of services, public support and local financial backing. Quite apart from the wider range of services received through a program stressing community services such as consultation, community planning and promotion, in-service training of community professional groups and social science research, the program by the very nature of its activities is highly visible and known to many key figures locally. The details of clinical services, by contrast, are never known. They are (as they should be) strictly confidential. Few then learn of the value of this service; the client is seldom outspoken and those who are to provide financial backing have but a statistical report and formal description of the services for consideration. It is a difference which may well be critical.

Services do not operate properly without sufficient fiscal support and reasonable assurance of continuity, while insufficient staff or facilities results in qualitative as well as quantitative program curtailment. Modern programming in the community mental health field is supported by some forward-looking legislation(20) that typically, on a matching-grant basis, leads to a partnership between state and community with the dual advantage of central leadership and local involvement. Local identification and responsibility is encouraged, leading to a more flexible adjustment of service in keeping with local needs. Then too, within budgetary limits, expenditures are subject to local determination where the communi-

ty may place greater value on professional talent and service because they seek it.

The cost of staffing may seem higher, for decentralization requires a greater number of costly well-trained personnel since more responsibility is delegated. Turnover is generally less, however, and the effective productivity of smaller quality units higher.

A larger proportion of cost is allocated to personnel (who do the work) rather than being tied up in equipment and major capital expenditures (buildings). In the Minnesota program, salaries typically account for 80% of a mental health center's budget, while the total annual cost per capita, for the area served, at full scale operation is only 90¢ to 95¢. In terms of cost per hour based on total expenditures and total professional hours in fiscal 1960-61, the median hourly cost was \$9.77 while local cost was under \$5 per hour. Considering the extent of service, it seems an excellent return.

PROFESSIONAL PARTICIPATION

Community mental health programs are designed to provide a broad range of services at the local level. The open-ended, complex and flexible nature of these programs, however, calls for fully trained personnel in all disciplines. There is no institutional control to fall back on, no available professional senior to turn to; "you are it," you stand or fall on the ability to assume responsibility, provide service, cooperate with others and "fit in" with the community.

The diversity of local demands and problems underscores ability and accomplishment more, in effect, than professional background(18). Also, particular abilities and talents do not necessarily follow professional stereotypes in hierarchial fashion, nor definition of function by profession. Generalization frequently required on the part of staff may be one factor accounting for the less strict division of roles and responsibilities among professions in this type of program. Professional growth and maximum achievement, however, are encouraged by delegation of responsibility. The opportunity inherent in a diversified program for utilization of training and skills not only precipitates growth, but also facilitates recruitment, provides greater job satis-

faction and encourages tenure. The administrative task is to create a climate in which each staff member is free enough and challenged enough constantly to precipitate himself into just manageable difficulty(9), an expectancy of excellence which leads to its pursuit. Quite apart from the impact this may have on the pace, nature and direction of program development, it creates a favorable professional climate, in turn lending desirable reinforcement to the service.

Even before it was so clearly documented by Albee(1), the severe professional shortages in the mental health field were widely felt, if not known. In the face of the magnitude of this dilemma it is incredible that greater measures have not been taken in both the recruitment and training of personnel. The modest "indenture-stipend" programs, now fairly common, only scratch the surface. What attempt is made to heighten the potential interest of the undergraduate, let alone those in high school? And few are the mental health services that have well developed training programs in coordination with the universities for the main mental health professions. To project the continuation or development of a network of services without an active plan for and role in training is rather irresponsible. Are we too busy with the difficulties of personnel shortages to take measures to solve the problem?

A frequent stopgap is the "hand-over-hand" competition with neighboring mental health services for personnel. Even this expedient which only shifts the shortage fails because there is failure to appreciate that the competition for such manpower is basically not with other comparable services but with industry and private practice(4). Moreover, some services, despite the noise from wheel-spinning, have not yet really answered the prime question: Do they really want well qualified psychiatrists, psychologists, social workers and others—and all that this implies?

SERVICE AND SALARY

All too often, neither training, responsibilities, conditions of employment nor salary bear a realistic relationship. The more common pattern is: professional standards, too

low ; responsibilities, too varied and far in excess of training ; personnel, equipment and space, insufficient ; and salaries, non-competitive. There are many very serious ramifications to this. Two conditions seem most common :

1. A salary unlikely to attract well qualified personnel : to fill positions, professional standards are progressively lowered, but once inferior staff has been recruited, the agency is deprived of the caliber of staff originally wanted, and more serious, the least qualified are the least mobile. Intended responsibilities become inappropriate. Whoever heard of someone with a year or two of medical training (incomplete training) being recognized as a physician ? The same principle holds equally for psychologists, social workers and medical specialists.

2. Seduction by fringe benefit : the basic position and/or remuneration is uninviting. By recourse to various "arrangements," the wrapping for the package is made attractive. Once recruited, the man's talent and identification are divided, his income cumulative. And the basic task ?—probably still unmet. This solution is an insidious one, having the seeds of self-destruction. It leads to professional drift away from the agency and obscures identification. Service becomes less reliable and the arrangements progressively more difficult to justify—certainly to the public. Both service and staff are prostituted, yet eventually may be held accountable.

PROFESSIONAL STANDARDS

Suppose we accept the notion of the "team" and that various professions can make a serious contribution to mental health services. If so, all must be fully trained and sufficiently experienced for an atmosphere of cooperation and respect to prevail, indeed, be possible. The conviction that only fully trained persons can adequately bear full professional responsibility results in comparable competency among the professions and artificial hierarchies tend to dissolve. Administrative responsibilities may then be determined on a "best man" basis. Responsibility is thus directly

related to talent and an effective and efficient service can be expected.

Paradoxically, it might be added, that though mental health personnel, with all too few exceptions, exhibit a general disinterest or dislike of broad administrative and fiscal matters, the number of able or qualified administrators falls substantially short of those who believe that the role is properly theirs. Academic training in psychiatry, psychology or social work is rarely germane to administration. Thus, it is difficult enough to secure an able administrator from the three professions, let alone any one.

When we deal with services, positions and qualifications, we are faced with the trials of job classification or merit system procedures. The aim is very clearly an orderly arrangement by duties and responsibilities of all positions(4). But this fair and logical aim is all too often fraught with two major handicaps. In the first place, technology and the professions are in fairly rapid change with the result that Civil Service structures lag behind professional developments and there is often a rigidity, because of the mere size of the structure, that impairs adjustment to professional developments or makes it almost impossible to accommodate them. More serious, however, is the strong conflict in value systems between the ways in which competence is assessed by the profession and by Civil Service(13). This is most evident in the two differing views of a college degree, particularly a graduate degree. The common professional assumption that specific academic achievement per se qualifies an individual for a job is a presumption not always shared by Civil Service. In fact, professional requirements are often considered discriminatory, supposedly blocking the appointment unjustly of persons who, it is averred, can do the job though they have not met the usual professional requirements.

This procedure runs contrary to the notion that with intimate knowledge and experience, a profession knows its resources and limits best. Rather, the classification officer becomes the ultimate judge. Regardless of the inaccuracy, this is hardly an approach designed to elicit the cooperation

and interest of well qualified (by the professions' standards) personnel.

In some professions, notably medicine, and in some services, such as Minnesota's Community Mental Health program(21), this conflict has been solved by resort to legislation (or Rule and Regulation) of the professional standards. Any amendments, as deemed necessary, may then be sought directly by the professions or the department concerned. In setting standards for public service in this way, it is likely that the minimum requirements will be high and the maximum open. The only clear way for change then is up; that is, improved standards and standards having professional recognition.

SUMMARY

Comprehensive community mental health programs follow the pattern of public health philosophy which places the need for community service paramount to individual considerations. Public support and professional participation are seen as the cornerstones of such a program, but both the social and professional aspects are influenced by factors which we tend to overlook. In the community mental health field we have been all too prone to develop services without consideration to solving the vast community problems created by a wide range of disordered behavior. Proper integration and control of local services could have a preventive impact. This must become the ultimate goal, for without it, there is no solution.

A COMPARATIVE VIEW OF AGGRESSIVE BEHAVIOR¹

LINCOLN D. CLARK, M.D.²

Freud published his dualistic classification of instincts about 40 years ago. Since that time, concepts about hostility and aggression have had a particularly important place in psychiatric theory. Many psychiatrists have moved away from Freud's original view that aggressive or destructive tendencies were primary human instincts or at least have been reluctant to call them "instinctive." However, even at the present time, aggression is commonly thought of as a motivational state or drive which appears either overtly or in a variety of disguised forms in human behavior. Like other drives, it is conceptualized as something which can either be acted out or sublimated, repressed, displaced, or otherwise defensively manipulated. Aggressive impulses turned toward the self are used to explain depression and suicide.

In view of the important place accorded to aggression by psychiatrists, it is not surprising that a number of workers have been led to study the aggressive behavior of lower animals. A variety of species, including fish, rodents, ungulates, carnivores, as well as primates, have been investigated under both field and laboratory conditions(1). An interesting feature of this literature is the remarkable unanimity among investigators about the nature of hostility and aggression in animals. The research described in this paper, while novel in some aspects, mainly confirms the findings of others. It will serve to illustrate the kinds of information which can be obtained from research in comparative behavior.

The subject of the experiments to be reported is the Northern Grasshopper Mouse, *Onychomys leucogaster*. Several groups of these animals, along with other species of wild rodents, were obtained for laboratory study in a search for animal behaviors which might serve as screening

tests for the psychopharmacological effects of drugs. In the course of this survey, the unique value of this mouse for experimental study of agonistic behavior was incidentally found.

Onychomys leucogaster is a stocky rodent with a short tapering tail. Adult mice weigh 25-40 grams and are 5-6 inches from the tip of tail to nose. The under parts of the body are white, the upper portion grey in juveniles, brownish to pinkish cinnamon or buff in adults, and again grey in old age(2). The subspecies studied was *utahensis*, originally trapped in semi-arid, sagebrush covered terrain west of Salt Lake City, Utah. They had been in captivity for several generations when first studied from a behavioral standpoint.

Onychomys are unusual mice in that they are carnivorous and predatory. Despite their small size, they trail, stalk, seize other mice and kill them quickly by gnawing into the brain stem at the base of the skull. As predators, they are reported to range over a wider area than other mice, preempting the burrows of other small animals as they move from one locale to another. In terms of aggressiveness and method of killing, *Onychomys* have many similarities to the weasel and to a lesser extent to the shrew, whose limited vision and olfactory sense make him a less effective predator than *Onychomys*.

These mice have a variety of features which should encourage investigators to use them as experimental subjects for studying aggression. First, they are small, easily handled, and inexpensive to maintain in the laboratory. Secondly, because they are naturally predatory, their aggressive behavior is easily elicited, continues with minimum reinforcement, and persists in stable patterns for long periods. Thirdly, episodes of fighting can be readily quantified since this behavioral pattern is highly predictable under a given set of conditions and offers easily recorded endpoints(3). In most of the studies in this paper, the measure of aggressive level was the time elapsing between the introduction of the

¹ Presented at the APA Western Divisional Meeting, Salt Lake City, Utah, Sept. 1961.

² Assoc. Professor of Psychiatry, College of Medicine, University of Utah, Salt Lake City, Utah.

victim and his death. This was supplemented by a simple rating scale to indicate frequency and persistence of attacks. Finally, it was found that experiments could be devised to study the effects of prior experience and social interaction upon the aggressive behavior of *Onychomys*.

EXPERIMENTAL STUDIES

The mice were raised in colony cages (18" x 18") in groups of five. Under these conditions no fighting occurs. Such animals are designated as "novice" since they have had no fighting experience. If care is used to avoid the stimulus conditions which precipitate fighting, mice of other species can be introduced into colonies of novice mice. Furthermore, novice mice may be placed in separate cages and paired with alien mice. For descriptive purposes, these are called respectively, "colony coexistent" and "paired coexistent" groups. An interesting sequence occurs when the strange mouse is first introduced. *Onychomys* immediately approaches and, after sniffing the body of the strange mouse for a few moments, "acts out" the method of attack characteristic of his species. He approaches from the rear, grasps the stranger with front and rear legs, and places his mouth at the base of the skull, even taking a few playful nips. After two or three repetitions of this performance within the first few hours after the stranger's arrival, the behavior disappears, coexistence ensues and different species share the same nesting area. Mice which have coexisted with *Onychomys* include a variety of both wild and laboratory mice.

An early goal was to determine conditions which precipitated aggression, reenforced it, or conversely inhibited it. We first placed an *Onychomys* and a potential victim together under a one liter beaker inverted on an electrified grid. A few mild shocks induced immediate attacks. It was soon found that shocks were not necessary and that confinement in the beaker for 5 minutes once a day led to lethal attacks on the first to the eighth trial. The mean for 13 animals was 3.6 trials. Non-lethal attacks invariably appeared during the first trial. The tendency in early trials was for *Onychomys* to spend part of his time exploring

and seeking to escape from the beaker. Exploratory activity, however, soon disappeared and *Onychomys* would concentrate on attacking his companion.

Any environmental change which excites *Onychomys* will increase his aggression. The more active the victim, the more he will stimulate *Onychomys* to attack. The survival value to the potential victim of catatonic immobility or "playing possum" is dramatically evident in these experiments. Artificially reducing the excitability of the victim by tranquilizing him with chlorpromazine will prolong his survival time. The effects of electric shocks have already been described. Tweaking *Onychomys*' tail with forceps or rattling the beaker similarly agitate the animal and heighten aggression.

In summary, the aggressive behavior of *Onychomys* is a response to stimulus conditions which heighten the excitability of the animal. These include painful stimuli, sudden changes in the environment, vigorous activity on the part of the victim, and confinement in a small space. The nature of the "emotional" state induced by these conditions can, of course, only be inferred. However, it is reasonable to assume that the experience of pain and unfamiliar environmental changes cause fear. The technique of confinement probably acts through the latter mechanism. Placing the animal under a beaker or progressively decreasing the amount of space available to the animal in its cage disrupts its territoriality. The concept of territoriality refers to the characteristic way in which animals distribute living space between one another and maintain separation from other species. Normal territoriality maintains a tolerable level of stimulus contacts with other animals. Conversely, reduction of living space below critical limits is emotionally disturbing to animals. In *Onychomys* this disturbance triggers attack behavior. By killing the alien mouse, *Onychomys* reduces its stimulus value to that of a corpse, restoring the situation to a more tolerable one. Attack behavior can also be precipitated in *Onychomys* by conditioned fear. This was accomplished by exposing the animals to buzzer and shock trials in a grid-floored plastic box. The buzzer or even the environ-

ment in which conditioning has been carried out will induce conditioned animals to attack a companion mouse with which they have previously lived in peaceful, paired coexistence.

The effectiveness of starvation as a means of initiating aggression in novice *Onychomys* in paired coexistence with alien mice was studied. Pairs of animals were starved from periods of 2-8 days. They were observed regularly but no aggressive behavior was seen. It can be concluded that severe starvation, even in this predatory animal, has little or no stimulus value for initiating aggressive behavior. On the assumption that fear as a factor precipitating aggression would be associated with sympathetic discharge, an effort was made to simulate the humoral aspects of this response by administration of epinephrine in various doses to *Onychomys* in paired coexistence with other mice. However, no signs of aggressive behavior were produced by treatment with this drug. This negative finding is again consistent with the general principle that internal, physiological changes are insufficient stimuli for the fighting response.

During early fighting experiences, if the victim is too large, vigorous or aggressive in response to attack and *Onychomys* is unsuccessful in his efforts to effect a kill, he will soon stop attacking. If the victim survives for 12-24 hours, peaceful coexistence ensues. If the victim mouse defends himself too vigorously or jumps about wildly in the confined space and accidentally knocks *Onychomys* about, *Onychomys* assumes an upright defensive posture and, if the trauma continues, will temporarily fall into a catatonic state. Such encounters can be produced by using the large, vigorous Pinon mouse as a victim. As an alternative to continued aggression, *Onychomys* may therefore cease attacking, go on the defensive, or withdraw into catatonic immobility. Even after the aggressive pattern is well established, it can be suppressed by repeated failures or systematic defeat. However, it is otherwise quite permanent. Animals which have had no fighting experience for over 6 months will attack and kill victims placed with them, though not with the

efficiency of mice regularly given opportunities to fight.

As in the case of other animals, *Onychomys*' fighting is strongly reenforced by success. Therefore, a series of easy victories increases aggressiveness and rapidity of kills. The size of the victims may then be gradually increased until *Onychomys* can readily kill mice which weigh twice his own body weight. The time elapsing between introduction of the victim and the kill may be as brief as 20 seconds. When fighting trials are carried out at regular intervals, at the same time of day, with victims of the same species and of approximately equal body weight, the time for the kill becomes sufficiently constant to be used as a baseline for studying the influence of various factors upon aggressive behavior.

So far, only preliminary studies in a small number of animals have been carried out on factors which might influence stabilized levels of aggression. However, the results are sufficiently interesting to deserve mention at this time. Total starvation for 24- and 72-hour periods does not increase aggressiveness. The effects of chlorpromazine given orally in doses of 16, 30, 32, 37.5, and 45 mg./kg. were studied. *Onychomys* is remarkably resistant to chlorpromazine. Although slight sedation appeared with dose levels of 16, 30, and 32 mg./kg., there was no evidence of behavioral toxicity, and the level of aggression and speed of kill were not significantly altered. However, 37.5 mg./kg. produced evident ptosis and slight to moderate ataxia. At 45 mg./kg., motor impairment was severe. While these animals did attack the victim, they did so less frequently and with less persistence and failed to kill during the 5-minute trial. It would appear that chlorpromazine alters fighting behavior in *Onychomys* only in doses which produce gross toxicity and that motor impairment is a major factor in their failure to kill the victim.

An even more interesting observation, however, was made when the fighting behavior of the animals was studied the day after a single fighting trial on chlorpromazine. To our surprise, in all of the 8 animals which received 16, 30, and 32 mg./kg. doses, the level of aggression was much increased and the time for the kill marked-

ly reduced the next day. This effect was most striking after trials at 16 mg./kg., but also clearly evident after 30 and 32 mg. doses. All of these animals had remained aggressive and made kills on their chlorpromazine trials. In contrast, all of the 8 animals which received 37.5 or 45 mg. doses were less aggressive the day following chlorpromazine and killing times were appreciably longer than pre-drug levels or did not occur at all during the 5-minute trial. There was no evidence of a drug hangover in the form of motor impairment to account for this effect. Apparently the experience of a successful fight, during which *Onychomys* is medicated with chlorpromazine in doses which do not impair his capacity to kill, powerfully reinforces aggressive behavior on the next opportunity to fight. By the second day after medication, killing times return to pre-drug levels. If animals fail to achieve fighting success because of chlorpromazine, the experience has an inhibiting effect upon aggression in the next trial, as would failure from any cause. These findings suggest an interesting hypothesis, i.e., the affective state of an animal at the time he performs an aggressive act modifies the reinforcing value of the experience for future behavior of a similar kind. It is possible that anxiety reduction from chlorpromazine during the aggressive act accounts for its enhanced reinforcing value. The converse, the effect of chlorpromazine upon the experience of defeat, remains to be systematically studied. However, the finding in animals which received 37.5 and 45 mg./kg. doses suggests that chlorpromazine does not reduce the inhibiting effects of failure.

The aggressive behavior of groups of 3-4 *Onychomys* has been studied in two types of colonies which differ in terms of the experience of the animals during the period when the fighting response was acquired. Both groups were trained to fight in a series of 8 trials under a one liter beaker over a 2-week period. However, the members of one colony were returned to their home cage between fighting trials, while members of the other were housed separately during this period and then rejoined to form a colony. Because of the marked behavioral differences which appeared in

these two types of groups, the first has been termed a "cooperative" and the second a "socially disorganized" colony.

The "cooperative" group lived together without internecine conflict as they had during the training period. Victims introduced to the colony in its 18" x 18" cage were promptly killed. The victim was hotly pursued by all members of the colony; several mice would share in the killing and would eat the carcass. While particular mice in the group were more aggressive than others and more often participated in the kill, all participated at times and no mouse was actively excluded. In contrast, when mice which had lived separately during fighting training were first returned together, a good deal of fighting occurred between members of the group. This reached destructive proportions. They suffered loss of ears and tails, 3 members of one colony were killed, and most lost weight. When a victim was introduced, members of the colony fought bitterly over which would make the kill. The dominant mouse was obliged to hold his competitors at bay or drive them into the nesting area before he could seize and kill the victim. Rapid kills occurred only when there was a markedly dominant mouse capable of achieving this feat. However, this dominant role could be maintained for only short periods and shifted from one mouse to another. After a kill had occurred, a period of 10 or 15 minutes of excited behavior would follow during which the *Onychomys* would attack one another. Accordingly, frequent introduction of victims intensified self-destructive aggression within the group.

At times when no clear-cut dominance was present, killing effectiveness was much impaired as the members expended their efforts sparring with one another. Under these conditions, some of the "victims" survived and established separate nesting areas where they coexisted precariously for many months. Other mice could be added to such coexisting colonies and might or might not be killed, depending upon the dominance situation at the time. Although the new arrival might be killed, previous survivors to whom colony members had become habituated would not be fatally attacked. It should be emphasized, however,

that this type of coexistence is considerably different than that which can be established with individual or group *Onychomys* which had had no killing experience. Under these conditions, the alien mice establish *separate* nesting areas and spend much of their time in hiding since they are subject to abortive attacks when they go too close to the *Onychomys*.

The above characteristics of the cooperative and socially disorganized colonies persisted without change for 6 months. The former remained a highly effective killing group even when victims were offered at intervals as long as 2 weeks. In contrast, disorganization and internecine conflict of the latter were perpetuated by periodic introductions of victims. It has already been pointed out that this procedure can lead to destruction of the colonies if repeated frequently.

The alternative form of the disorganized colony is one in which precarious coexistence with some victims is admixed with destruction of others and reactivation of conflict among the *Onychomys*. It is interesting that the survivors of self-destructive colonies are the less aggressive animals. It is true that these animals may have been subjected to repeated defeat in colony life. However, subsequent studies of their fighting in individual trials under conditions which should reinforce this behavior indicate that like the meek who will inherit the earth, they owe their survival to being less aggressive and thereby avoiding fatal encounters.

SUMMARY

A series of studies which illustrate the value of *Onychomys leucogaster* as a laboratory animal for study of aggression have been reviewed. The aggressive behavior of this animal follows a highly predictable pattern and can be readily quantified. Experimental conditions can be devised whereby it is possible to study factors which influence the first expression of this genetically determined behavioral trait as well as factors which reinforce or inhibit it once it has become established as a response.

Chlorpromazine was found to have an interesting effect upon the aggressive behavior of *Onychomys*. Medication with this

drug in dosage ranges which did not impair fighting ability because of motor toxicity markedly increased the reinforcing value of a fighting experience. A possible interpretation is that the affective state of an animal at the time of a behavioral response, in this instance an aggressive one, alters the effectiveness of the behavior in terms of reinforcement. Chlorpromazine presumably reduces the level of "anxiety" or fear associated with aggression.

Onychomys may also be conveniently employed to study aggressive behavior in social groups. Methods have been described whereby novice, non-fighting colonies of mice may be selectively converted into groups which coexist peacefully with other species, which cooperatively direct aggression toward aliens or which become socially disorganized and suffer from internecine conflict which results in the death of colony members as well as an impaired effectiveness in destroying alien animals.

CONCLUSIONS

This work, as well as that of others, enables one to draw a number of general conclusions about the aggressive behavior of vertebrate animals.

1. Aggression is a behavioral response pattern elicited by particular stimulus conditions. This response is in part genetically determined and is more readily elicited in some animal species than others. The adequacy of an animal's physical equipment for fighting, in comparison with that of its enemies, will, of course, determine how successful it will be in responding aggressively.

2. However, even animals well equipped for successful attack and genetically predisposed to aggression need never display aggressive behavior. It can remain latent unless elicited by particular environmental conditions and experiences. Moreover, even if aggressive responses become developed, the animal can alter its behavior to find a non-aggressive solution.

3. In other words, aggression is strongly influenced by learning. The experience of success in fighting reinforces aggression while absence of fighting or recurrent defeat decreases motivation to fight and the likelihood of future aggression.

4. The stimuli which elicit aggression arise

externally and represent environmental threats to the security of the animal. These stimuli include infliction of pain and situations which generate anxiety or fear. An aggressive response, if successful, restores emotional equilibrium; the threatening object is driven from the field of interaction or reduced in stimulus value through death.

5. In contrast with ingestive or sexual behavior, there is no evidence to support the view that there is any instinctive or physiological need for aggression. It is not an instinct or even a drive in the usual sense of these terms. It is not something which is quantitatively reduced by being expressed or acted out.

6. The structure of animal societies is such as to limit destructive levels of aggression. During infancy, the animal passes through a period of not fighting or of repeated defeat by more mature members of the group. This phase of "primary socialization" is followed in adulthood by various forms of dominance hierarchies. These result in an overall decrease in fighting. After the initial conflicts, which are practically never lethal but are required to establish the dominance order, the relationships between individuals stabilize on peaceful terms. Occasional threats by more dominant animals are reacted to with submission or avoidance by those lower in the hierarchy.

7. The phenomenon of territoriality, the system whereby animals distribute living space and food supplies and stabilize the level of stimulus contacts with other animals, is also of crucial importance in reducing aggressive behavior. On the other hand, violation of habitual territoriality can precipitate aggression.

8. A group of animals disorganized in

terms of either social or geographic factors is liable to develop a higher incidence of destructive, aggressive behavior.

9. Human aggressive behavior in our society more often appears as verbal attacks or threatening attitudes than physical violence. However, it is elicited by external threats to security or self-esteem and, if successful, serves to drive the threatening person away or figuratively to cut him down to size through verbal defeat or humiliation. The human animal becomes more aggressive when aggression is successful.

The degree to which these conclusions affect thinking about aggression will depend upon acceptance of the value of research in comparative behavior. A reasonable point of view for the psychiatrist is to recognize that there are obvious differences between the behavior and behavioral development of man and any other animal with which he might be compared and that naive analogies are hazardous, and yet accept the fact that there are critical similarities which can be so analyzed as to expand the scientific basis of psychiatry. This is no real reason that research on animals, correctly conceptualized, should not be as valuable to psychiatry as it has been to other life sciences.

BIOCHEMISTRY, GENETICS, AND THE NATURE-NURTURE PROBLEM¹

BERNICE T. EIDUSON,² SAMUEL EIDUSON, AND EDWARD GELLER³

In a recent symposium on concepts in biology Spuhler said, "You hear very little now, outside of textbooks, about the heredity-environment controversy; the working people do not worry about this much anymore" (1). Psychologists arrived at a similar attitude 20 years ago. During the 1930's a large number of psychologists had been experimentally trying to parcel out the influence of heredity and environment in intelligence and other behavioral traits. Their results turned out to be equivocal; and this made most workers feel that research in this area was inevitably dogged by uncontrollable errors, statistical difficulties and questionable controls (2). Anderson, in summarizing the data, suggested that nature-nurture was an unproductive area of research and advised psychologists to turn away from it, advice which most took.

In the intervening years, only a few papers have suggested its reconsideration. In these the trend has been to point out our need to conceptualize the heredity-environment problem differently, in ways that are more in line with some of the present theoretical formulations of biology, for example. If we followed these formulations, the question would no longer be simply how much heredity and how much environment, but rather the question would turn to their relevant contribution on each of the various levels or strata in terms of which the organism is conceived (3). Some psychologists (4) have suggested that perhaps behavioral data can contribute something to the mode or the mechanisms by which heredity and environment interact, for the fact of interaction is generally accepted, albeit more out of a

feeling of helplessness at the complexity of the heredity-environment relationship than out of any real knowledge of the nature of the interplay.

Today some of the new experimental work in the biological sciences—embryology, genetics, biochemistry—is providing data about the nature-nurture factors and their interaction on the molecular level which elucidates the problem as it has been posed in regard to behavior. In the light of the new information, the assumptions generally held by psychologists about heredity turn out to be outdated, and even incorrect; and when the biological data about environment are considered along with the new findings in the behavioral sciences themselves even the conceptions about the nurture side demand revision. We had set out, in preparing this paper, to summarize the experimental data that we felt were beginning to detail the developmental processes, and that were already casting the heredity-environment issues in new light. However, this main intent turned out to have an intellectual by-product which began to interest us very much. Particularly as we reviewed the nature of the interaction between the nature-nurture factors, we became aware that many convergences and possible identities existed between phenomena and process on the biological level, and these on the psychological. In fact these turned up so regularly in the aspects we studied that we began to consider whether one model which had proved so useful on the molecular stratum could not be profitably transposed to the molar. We have taken the liberty of presenting our speculations about this at the end of this paper.

First a look at the new and enhanced concept of the heredity mechanisms to which biological scientists are directing our attention: until recently psychologists have been prone to consider biological or constitutional factors as constants, establishing the limits or boundaries of behavior, but reflecting none of its variance or uniqueness,

¹ We wish to thank Dr. Arthur Yuwiler of the University of Michigan and Dr. William C. Beckwith of the UCLA Medical Center who read the manuscript and made many helpful comments and criticisms.

They have looked to environmental contacts for providing the bulk of the organism's information content. Freud, for example, saw the infant as the passive recipient of stimuli from the outside world who learned his characteristic modes of thinking and reacting only when he began to take stock of the environment and perceived it through the processes of incorporation(5). Hebb has drawn attention to the same tendency among other psychological schools(6) to conceptualize motivation and drive in ways that are out of line with current physiological data. Elsasser suggests that this viewpoint stems from the strong influence of Darwinian notions on our scientific thinking(7). He, by contrast, feels that the bulk of the individual's information content is endogenous; and support for his position comes from the new genetic data which show that the hereditary mechanism itself can account for—at least has the potentiality for accounting for—all the vast differences that we see expressed in behavior(8). Biologists have now been able to show decisively that man has 23 pairs of chromosomes and they have been able, mathematically, to work out the possible combinations of chromosomes that can be transmitted by the parents to the child(9). It appears that the possibility for hereditary likenesses among children—even in the same family—is very small. The likelihood for 2 non-identical siblings in one family to have exactly the same genetic characteristics is only one chance in 64 trillion; the probability that two unrelated individuals will share the same genotype turns out to be effectively zero(10). While identical twins have the same genotype by definition, in fraternal or siblings there is still no question that the possible genic combinations make, as some geneticists have said, this inheritance game the "greatest lottery of all."

Moreover, we have thought until recently that some variability in heredity resided in discrepancies in the number of genic components transmitted from parent to child. Recent experimental work has shown that there are certain pathological disturbances which are produced by too many or too few chromosomes. Mongolism is one such disorder, the result of one extra autosomal chromosome. Klinefelter's and Turner's dis-

eases which result in sexual aberration in boys and girls are the results of one extra sex chromosome and one too few sex chromosomes respectively—and Tarjan and his group at Pacific State Hospital in California are finding that mongolism and Klinefelter's and Turner's diseases may actually be related to each other(11).

However, more pertinent a factor in normal and abnormal development is the composition of genic patterning, the sequential arrangement of the genetic components, and this turns out to be a highly intricate process, which is mosaic-like in its potential for variability. This has been most clearly elucidated in biochemical genetics which is concerned with genetically-determined enzymes and thereby with the control of certain aspects of metabolic reactions. The "one gene: one enzyme" hypothesis, that each gene is a coded template by means of which one specific enzyme (more generally, protein) is synthesized, was elaborated some time ago. This formulation proved to be a first wedge into the understanding of the mechanisms of certain intraorganismic functions, but this has been shown to be only part of the story. Subsequent investigation with specific metabolic systems has shown that many reactions are not exclusively determined by the presence or the absence of the appropriate enzymes(12).

Few geneticists today uphold the hypothesis of the autonomous gene. Mendel originally postulated the notion of dominance as a principle determining whether or not a trait would be manifest in the phenotype of an organism, but techniques were not available to demonstrate the actual mechanism. Technological advance has resulted not only in a general investigation of this phenomenon, but in evidence indicating a host of other intra-genetic relationships: suppressor genes and modifiers, which act as intensifiers, diluters, inhibitors; genes which exert their influences at early stages of development while the presence or identification of others can be recognized only when the organism reaches maturity; gene changes which may result in more than one observable change in the phenotype. For psychologists, it is particularly interesting to note that what changes are observed in this latter phenomenon—which is called pleiotro-

phy—turns out to depend on the knowledge of the observer and the intensity with which the search was pursued (13) !

The now well known "inborn errors of metabolism" were the first inroads into the large area of pathological disturbance which we now accept as genetically determined (14). But with their exploration has come a host of syndromes which seem to be playing into a myriad of disorders in which classification of neither syndrome nor source is simple (15). Medical genetics has been able to elaborate many disturbances which are now recognized as genetically bound. As metabolic pathways are systematically mapped, their intricacies and circuitries become apparent, and the possibilities for distortion of function and resultant pathology seem to multiply with the complexities of the intermediary processes. In studying mutant individuals with hemophilia, for example, it has been shown that at least 9 gene-controlled substances are required in the blood-clotting mechanism, and that each of the trace proteins involved may become dysfunctional through mutation (16).

Furthermore, medical genetics has shown that one cannot tell from the manifest behavior what has been the cause of the disturbance. In one individual an environmentally produced agent can lead to pathology ; while in another, an equivalent syndrome can be caused by genetically induced substances. Hemolytic anemia, for example, can be induced by certain drugs which makes it look environmentally determined but yet it is a genetically bound disorder. To further complicate the picture, the overt disease picture may give no clues as to its genesis.

The wide range of individual differences found in this work has alerted biochemists to the biochemical differences among individuals. We have long been familiar with inter-individual physiological and anatomical differences, but until now attention has not been turned to how these differences in turn affect function, what intra-systemic differences exist, and how these make their appearance. Williams, in a systematic compilation of incidences of biochemical individuality, has shown, as one example, that the urinary amino acid profiles of individuals are considerably different (17). Interestingly

enough, identical twins show patterns much more similar than do fraternal twins and siblings.

The recognition that one form of mental deficiency could be a concomitant of the inability to convert one substance to another to form the proper metabolic product in the now well-known phenylpyruvic oligophrenia disorder was an early encouragement to look for mental disturbances in genetic metabolic function. The subsequent search showed that this was only one of many ways in which interference with the necessary enzyme products can occur. Biochemists have found also partial lacks in enzymes ; or overproduction of enzymes ; or that metabolites are shunted off in such ways that they do not quite do their proper duties at the right time or at the right place. As the number of physical and mental disorders that can be reduced to inborn metabolic errors is steadily increasing, investigations are developing increasingly sophisticated models of intra-organismic function, and while our conceptual framework permits us to speculate that phenomena which exist side by side are probably highly correlated with each other, there are many more phenomena which are still extremely diffuse and vague, and as yet indefinable.

As the genetic factors do not operate in a vacuum but in an environment, attention has simultaneously been drawn to nature of the host, its participation in the intra-organism processes, and in the resultant behavior. Here, researchers have been confronted with an active factor or set of factors, which condition not only what is genetically determined, but often whether a genetic characteristic will make its appearance, and when. The biological studies make it quite evident that environment can no longer be defined as something outside the organism which affects or becomes part of the organism by internalization; environment must include intra-organismic factors as well, for the nature-nurture interaction is so meshed and interdependent even on the prenatal level that it becomes impossible to determine what is heredity and what is environment. Study of prenatal development has shown that development is a long process of continuous changes, starting with a given genetic array acting in a given en-

vironment. The first interaction product then constitutes the background (or the environment) for the next step of interaction with the environment. In the case of a given cell, this includes the interaction product of other cells, and in this manner all future reactions then are codetermined by all preceding steps and hence also by genetic endowment. Thus, at whatever point one arrests the sequential reactions for study, one can no longer—except arbitrarily—point to certain factors as genetic and others as environmental. As Weiss has said, there is no sharp dichotomy—even prenatally—between geneticists and environmentalists (18).

With the increasing knowledge of what goes on inside the organism, biologists have come to recognize the importance of the dimensions of time and space for even cellular phenomena. In the study of different metabolic needs of different cells, they have recognized that there are certain periods of sensitivity in cellular reactions—times at which things happen or interactions take place (19). Thus, even if all the structural components necessary for certain reactions to take place are in order, it is conceivable that these reactions just may not progress at the rate necessary to allow for a subsequent step to be instituted or systematically meshed with the first—or it is possible that certain reactions are physically separated by even so little as a fraction of a micron and that this may be enough to modify seriously a necessary and sequential relationship. Such dimensions are extremely significant in the elaborate system of regulatory relationships that exist in many metabolic processes. Feed-back mechanisms, as in the case of hormonal regulation of pituitary response to stress, are well known. It has been found, additionally, that in nervous tissue a chemical substance apparently may induce that enzyme which it subsequently needs for its proper action in transmitting electrical impulses across the synapse (20). Acetylcholine, for example, functions as a chemical mediator. Once it has so operated, however, it has to be destroyed (hydrolyzed) so that the proper termination of the membrane depolarization can take place. Acetylcholine has now been suggested as the embryonic determinant for the elaboration of acetyl-

cholinesterase, the enzyme which hydrolyzes it. Therefore, one sees here not only a built-in feed-back system which permits proper functioning, but also a mechanism which appears to demand a more complex interpretation than simple feed-back.

From the biologists we are also getting a picture of the kind of differential growth processes that are found prenatally. These are similar, we think, to the different capacities of the organism that have different maturational rates on the behavioral level. While in tissue growth there are presumably some metabolic requirements that are held in common for all tissues, the prenatal group processes do proceed differentially in certain tissues and cells, so that different tissues develop with different metabolic needs (19). Some growth agents seem to effect only specific partial processes; others have a generalized effect. Some agents effect certain growth processes only at times when certain metabolic needs can be interfered with and these same agents will be ineffective at other times. Thus, the "sensitivity periods" may be also described as times when the likelihood of throwing processes out of gear seems to be much more probable. We learn, too, that different tissues progressively develop different metabolic needs, which permits us to elaborate the notion of differential growth processes on the cellular level.

These "sensitivity periods" of the biologists are particularly interesting for they may be counterparts for the "critical periods" in development with which psychologists and ethologists are now becoming increasingly absorbed. Psychologists have found that there are specific times in ontogeny, or specific states, during which certain types of behavior normally first appear. If these times pass without the experiences having taken place, changes, and sometimes lags, in development occur which are never recoverable even though the "right" experiences are presented later. Lorenz's work on imprinting (21), and Thorpe's work (22) on bird songs have independently pointed to the importance of specific times for the occurrence of some kinds of species specific behavior which subsequently becomes indelibly stamped as part of the psychological armamentarium of the animal. Once the

time for experiencing this behavior has passed, its learning subsequently never takes place.

It should be noted, however, that biochemical and biological maturation time may not be synonymous with chronological time, as one of us (S.E., 23) and others have pointed out. S. Eiduson and E. Geller and their colleagues have been working with new-born chicks to see how various biochemicals and biochemical systems develop in the new-born chick brain. They have found that chicks differ with respect to the times at which certain biochemical substances make their appearance in the brain (unpublished data). Also, Karki, Kuntzman, and Brodie(23) have found that new-born rats have low levels of brain noradrenaline and serotonin. In 2 weeks time the levels of these substances have reached 40% and 70% respectively of normal. In about 7 weeks after birth, the values are those of the mature animals. However, different chicks and different rats of the same age differ with respect to the concentrations of these substances in the brain. Therefore, if one were interested in those aspects of brain function which involved noradrenaline and/or serotonin, it would be erroneous to assume that chicks and rats of the same chronological age were all comparable with respect to noradrenaline and serotonin levels. Chronological age and biochemical or biological age may actually be different so that it might be much more nearly correct, in comparing the chicks and rats, to group those that had similar concentrations of these amines, rather than those that were the same number of days old.

Considerable behavioral work on very early learning has emerged as scientists have given up their long indulgence in "instinctive behavior," which seems to have cloaked certain early learned behaviors which were considered innate since they seemed to be species specific(24). When this "instinctive behavior" has been exposed to study, results have shown that even in those areas of behavior where the effective external influence may be practically nil, and where the behavior seems essentially unmodified by experience or unresponsive to environmental manifestation, the way that seemingly innate behavior is expressed

or the conditions under which it is expressed depends upon experience(25). On whom the animal imprints, for example, is determined in some species by the environment, even if the fact of imprinting is not. The crucial importance of just this "environmental condition," or the person or thing imprinted, becomes evident as we see that this, and not the fact of imprinting by itself, determines in some species the character of adult sexual behavior in later life (21). Portielje, the curator at the Amsterdam Zoo, a trained zoologist, raised and had a male South American bittern imprinted to him. The bittern was subsequently placed in a cage which was covered very carefully. A female bittern put in the cage was his constant and only companion. Although at first the male would have nothing to do with the female, he finally accepted her and for two years subsequently the pair lived together. They were not further exposed to any other animals or human beings, even being fed through the cage. The animals mated and hatched a number of broods together. Two years later the curator to whom the male bittern had been imprinted in infancy entered the cage and the male bittern saw him for the first time in these two years. When the keeper entered the cage the female bittern happened to be sitting on a nest of eggs, but as soon as the male bittern saw the curator he chased the female off the nest and proceeded to try to woo the curator and to inveigle him onto sitting on the nest of eggs. He showed all of the usual nest relief and social behavior toward the curator. Needless to say, that brood of eggs was never hatched(26)! This example illustrates that a behavior like imprinting that is thought to be genetically determined is very much dependent on the sequential development of the organism for the character of its expression. However, it illustrates as well that whether a genetically-bound behavior is expressed at all is similarly dependent on the experience to which the organism is exposed after birth. The absence of a necessary stimulus which serves as a releasing mechanism may make it appear as if the behavioral trait were never transmitted genetically at all; or the absence of a later releasing stimulus may make what

appeared to be an inevitably formative experience have no significance in adult life.

The cloak of ambiguity which "instinct" had thrown around early learning has had the further effect of drawing attention away from such factors as intra-uterine environmental conditions which influenced development. However, we today are becoming increasingly cognizant of the dependence of the phenotype on certain environmental conditions in the fetus such as nutrition and temperature. Ephrussi and Herold have shown that the phenotype expression of drosophilia is temperature sensitive: W^{b1} flies have brown eyes at 30° and red-purple at 17° (27). Goldschmidt produced many phenocopies in wild type with temperature shocks (28). Thus, it is impossible to regard all intra-organismic phenomenon as genetically determined, and therefore not susceptible to environmental influence. This position has received support, too, from the recent attempts to show the effect of environmental influence during the gestational period. Ginsberg and Hovda transferred fertilized ova from the female of a strain of mice, inbred for susceptibility to audiogenic seizure, to the uterus of a female of a seizure resistant strain, and found that the resulting young showed an intermediate susceptibility (29). Thompson and Hochman changed the intra-uterine environment and found differences in the emotionality of rats which they speculated might be due to possible changes in fetal material in the blood stream (30). In a water maze learning situation, Thompson and Sontag showed that offspring of parent rats who were subjected to seizure were slowed in their response to this same task (31).

As the experimental data on the nurture side of the paradigm continue to support the biological work showing the early and inevitable interaction of nature and nurture, the definition of what is learned becomes more blurred than it once seemed. Previously, psychologists were very ready to label as learned those facets of behavior which were separate from central nervous system growth, responsive to experience and manipulation to change or extinction, characteristics which were distinguished by their variability and mutability, in contrast to hereditary mechanism which was more

fixed and constant. This whole notion has been shown to be inappropriate in recent years. Sperry, the psychobiologist, tells us that in individual development the central nervous system must be sufficiently complex for coordinating any level of behavior when behavior begins, and this inevitably involves learning (32). Thus, learning is indistinguishable from CNS growth.

The definition of what is learned has also become less clear-cut as we have become aware of how much learning takes place without our being conscious of it. Experimental work, in discrimination and perception in both animal and human subjects, has suggested that the absence of normal amount of stimulation during developmental periods may result in an inability to respond effectively to sensory and perceptual cues when these cues become available. While much of the perceptual data is derived from studies of the visual modality, evidence demonstrates similar results with other sensory modes. The work on infant chimpanzees done by Nissen, Chow, and Semmes is in point (33): for when the chimp's normal tactual experiences on his own body and his environment were interrupted by placing mailing tubes over his hands and feet, no failure in development of primary sensory equipment of the skin was noted, but subsequently somesthetic learning and localization of the tactual stimuli were defective. This implied that more or less random tactual experience is necessary for the normal development of somesthetic perception. The experiments on pecking behavior response in chicks raised in darkness with consequent deficiencies in motor and sensory development is similarly vivid, in that such chicks never learned to peck and so were unable to feed themselves in times of starvation although they stood in the midst of plenty (34). The deprived and enriched environment studies on dogs and monkeys not only show how much facilitation is affected by conditions of early learning, but also point to the crucial period in development—the age—at which the deprivation or enrichment takes place (35). With human subjects one gets additional evidence that seemingly irrelevant and peripheral stimuli are taken in as part of the perceptual process and become part of

learning even though no direct learning experience seems to have promoted this. In the Poetzl experiments, for example, some parts of exposed stimuli were so unconsciously perceived that they were not subject to direct recall, even though it was apparent from dreams and subsequent conscious behavior that they had been part of the input (36). In summarizing the experimental work on effects of early experience upon the behavior of animals, Beach and Jaynes point out that with all its equivocality and undetermined reliability, the evidence suggests that habits formed in early life are persistent in adult behavior, that later perceptual capacities seem to be structured by early experiences, and that there seem to be certain stages in ontogeny during which certain types of behavior normally are molded and shaped for life (24).

Many years ago psychologists became aware that certain reactions like fear and rage, though admittedly unlearned, could not occur until the maturational development of the animal or infant had proceeded to a point where something in the environment could produce the innate response. Hebb has given the example of the infant chimp, who, though fearful of first strangers, only developed such fears after he had reached an age where he was able to recognize his usual caretakers (usually around 4 months) (37). Even the chimp reared in darkness to an age where fear is normally at its peak will not be disturbed by the first sight of a stranger until he has had the opportunity to learn to differentiate those who care for him daily.

Piaget's and Buhler's studies on the development of human thinking similarly have shown the importance of understanding the maturation of universal modes of thought for interpreting why a child handles experiences differently at different times in his early life (38). The child, a few months old, will not be distressed when an object is removed from view; he behaves as if the toy ceased to exist. But a few months later he actively searches for the toy and tries to remove the obstacle which has taken it out of view. The child's response and his possible range of behaviors depends on his developmental level, and on the corresponding "mental structures" available to him. The

child changes his behavior when the environment demands change; and yet the maturational level of the inherent "operatory structures" determines the nature of the response which will be made. The parallel to tissue differentiation seems cogent; for, as Weiss has described, during maturation, tissue increasingly differentiates and metabolic needs are correspondingly altered; but during this innately determined process, the nature of its differentiation is responsive to the local experience it meets, and to the environmental demands made on it (18).⁴

It becomes increasingly easy to draw such parallels with our extended knowledge—and increasingly provocative; and this has made us wonder if it would not be very profitable were such parallels systematically extended. We have been impressed that with new data, more and more convergencies appear. Pre- and post-natal growth processes seem to be analogous in many aspects; and also the nature of the interaction of genetic and environmental factors seems similar on both molecular and molar levels. Therefore, taking our clue from general systems theory, we wonder if formal identities do not actually exist between the biological molecular processes, and the behavioral (39). Rapaport's finding that there was comparability among diffusion of information (rumor) at the level of the social system, diffusion of matter or energy (infectious agents) in a biological system, and diffusion of neural impulses in an organ (the central nervous system) shows the value of transposing a hypothetical model from one systemic level to another (39).

We think that perhaps now we have the possibility of exploiting another model, that of biochemical genetics, for an exposition of the nature of the heredity-environment interaction on the behavioral strata. This would obviously be no simple job for psychology—for we would have to refine and recategorize some of our variables to make them suitable

⁴ While in this paper we have been primarily concerned with the local environmental changes and their effects on phenotypic expression of the genotype, there are as well many examples of extra-organismic (*i.e.*, psychological or sociological) alterations of genotypic expression. One such example is the effect of sensory deprivation on visual acuity.

for the kind of differentiation that such a re-study would involve. Yet one gets the feeling that the time—and perhaps the means—are now ripe, for we have evidence that the interlocked relationships of the nature-nurture factors is in itself important, and can be differentially broken down into distinguishable reaction patterns.

The biochemical genetic model has enabled the biologist to trace a number of pathways by which certain metabolic reactions proceed. Investigators can indicate what substances are given genetically and then show to some degree how certain sequences are dependent on environmental agents normally, where these agents impinge, how they facilitate reactions or interfere with them. Once pathologies are set in motion subsequent metabolic reactions can be studied and eventually whole enzyme systems are, or in the future will be, mapped.

We are suggesting that such a model offers the potential for doing a similar job in psychology. Psychology has always assumed that development is sequential and reflects both heredity and environment, but it has seldom considered that from the first post-natal moments, it is already looking at an interaction product with all behavior subsequent to birth representing simultaneously modification of this product and the emergence of a new interaction phenomenon. To all intents and purposes the psychologists have assumed that heredity and environment factors were like dependent and independent variables with one albeit affecting the other, but with the results of these interacting effects not being taken into account as the changed stage on which a second subsequent behavioral segment is acted out.

To apply the biochemical genetic model in psychology, we would have to start with systematic observations on early development, draw our variables from these observations, and begin to trace their evolution. Clinical data have information which could be abstracted about interferences, distortions and pathologies in post-natal growth processes—how they set in, the kinds of sequences that follow once an original abnormality or disturbance has resulted, and their subsequent development. Thus could

whole psychological reaction systems be tentatively mapped out. This seems to us to offer a possibility for plotting the ontogenetic sequences of psychological diseases—an important job that has long been overdue. The advantage of such a model for psychology is obvious; but additionally, if the convergencies between pre- and post-natal development continue to hold up, the psychological data based on post-natal observation and experimentation could conceivably offer to the biologist some clues about process in pre-natal development, and suggest to him some new avenues for research.

RELIABILITY OF PSYCHIATRIC DIAGNOSES :

2. A STUDY OF CONSISTENCY OF CLINICAL JUDGMENTS AND RATINGS¹

A. T. BECK, M.D., C. H. WARD, M.D., M. MENDELSON, M.D.,
J. E. MOCK, M.D., AND J. K. ERBAUGH, M.D.²

The psychiatric nomenclature as well as the process of psychiatric diagnosis in general has been "under fire" from many quarters. In a critical review of the systematic studies of the reliability of psychiatric diagnosis (3) it was pointed out that, while these studies consistently indicated a low level of interclinician agreement, they presented certain methodological problems which made the findings inconclusive. The author suggested an experimental framework within which systematic studies could be carried out to determine the effect of the relevant variables on diagnostic reliability.

The present study is the first of several investigations carried out within this methodological framework. For present purposes those variables which might influence the degree of interpsychiatrist agreement were controlled as far as possible. This required special attention to providing uniformity of the conditions of the investigation, for example, the nomenclature used by each psychiatrist, the minimum level of training and

experience of each psychiatrist, and the type of diagnostic procedures to be employed.

METHOD

Four experienced psychiatrists participated in interviewing the patients. The participating psychiatrists were all board certified in psychiatry and had important clinical or teaching positions. Psychiatrists A, B, and C had from 10 to 13 years of training and experience in psychiatry, while Psychiatrist D had 6 years in psychiatry; in addition, their experience was predominantly with outpatients while Psychiatrist D had experience chiefly with inpatients. The professional characteristics of each psychiatrist are summarized in Table 1.

Before engaging in the formal aspects of the investigation, the psychiatrists had several preliminary meetings during which they discussed the various diagnostic categories, ironed out semantic differences, and reached a consensus regarding the specific criteria for each of the nosological entities. The "Diagnostic and Statistical Manual of Mental Disorders" of the American Psychiatric Association (1) was used as the basis of classification. It was found that considerable amplification of some of the diagnostic descriptions contained in the manual was

necessary in order to minimize differences. After having reached agreement on the criteria to be used in making their clinical evaluations, the psychiatrists compiled a list of instructions to serve as a guide in diagnosis. They also agreed on a set of 22 indices to be used in assessing the depth of depression. (These are specified in another article(4).)

The psychiatrists were randomly paired so that each of the patients was seen by two different diagnosticians. The procedure was to have one psychiatrist interview the patient, and then after a resting period of a few minutes the other psychiatrist interviewed the patient. Each psychiatrist independently wrote out his diagnosis and rating of the depth of depression (none, mild, moderate, severe), and indicated the degree of certainty in making the clinical diagnosis (certain, fairly certain, uncertain). In the last 51 cases, the clinicians made a "differential diagnosis" consisting of a preferred diagnosis and an alternative diagnosis. After the second interview was complete, the pair of psychiatrists discussed the differences, if any, in diagnoses and assigned the reason or reasons for the lack of agreement.³

The patients included in this study were drawn randomly from new referrals to the psychiatric outpatient service of the Philadelphia General Hospital and the Hospital of the University of Pennsylvania. The patients were interviewed within a week after their initial administrative "screening." A total of 153 outpatients were examined. No

hospitalized patients were included in this series.

RESULTS

The percentage of agreements on specific diagnoses for each psychiatrist when paired with each other psychiatrist is summarized in Table 2.

The agreement rate was obtained by dividing the number of concordant diagnoses by the total number of diagnoses. The overall rate of agreement was 54%. The rate of concordance for the paired psychiatrists ranged from 33.3% to 61.4%, while the overall rate of concordance for the individual psychiatrists ranged from 45.3% to 59.5%.

It may be noted that the pairs to which Psychiatrist D was assigned had a consistently lower level of concordance than the other pairs. On the other hand, each psychiatrist, when paired with Psychiatrist A, showed a higher level of agreement than when paired with the other psychiatrists. An analysis was performed to determine whether there was any significant difference between the concordance rate for the individual psychiatrists. Psychiatrist A's level of agreement, exclusive of his pairing with D, was 60.6%; while Psychiatrist D's level of agreement, exclusive of his pairing with A, was 37.1%. The difference in percentages obtained by these two psychiatrists exclusive of their pairing with each other was significant at the .05 level.⁴ The differences among A, B, and C were not significant.

Another analysis was performed to de-

³ The results of the study of reasons for diagnostic disagreement will be reported separately (21).

⁴ In all analyses of the differences in the percentages, the standard error of the difference in the percentages was computed and compared with the obtained difference in percentages to determine the level of significance.

TABLE 2
Comparison of the Percentage Agreement on Specific Diagnoses
For Each Psychiatrist When Paired With Each of the Other Psychiatrists
(n=153)

B	61.4	—	57.5	45.4	54.8
C	59.9	57.5	—	33.3	50.2
D	57.1	45.4	33.3	—	45.3

termine whether the degree of agreement between the psychiatrists could be due to chance or was statistically significant. In order to compute the level of significance, it was necessary to establish first what the degree of agreement would be if chance alone operated. The rationale for the procedure employed to determine the expected agreement by chance was as follows: If each psychiatrist operated within a completely different conceptual framework, so that there was no common basis for selecting the nosological labels for a specific case, there would still be a certain percentage of their judgments which would coincide by chance. To determine the degree of chance agreement requires an estimate of the frequency which each psychiatrist would be likely to select the various diagnostic categories. Since it could be assumed on the basis of previous studies (15, 17), as well as in our own studies, that the diagnosticians would tend to exercise certain diagnostic preferences, it would be expected that, given a large randomly assigned group of patients, the proportions (base rates) for the various nosological categories would tend to follow the selective predilections of each psychiatrist. Once the proportions (base rates) for each psychiatrist were established, it would be possible to compute the percentage of diagnoses that would agree by chance alone. In order to obtain a more adequate estimate of the base rate for each psychiatrist, another sample of 205 cases was randomly assigned to the 4 diagnosticians* (each patient in this sample was seen by only one diagnostician). The base rate for each diagnostician was then obtained by computing the frequency distributions for the combined sample of 358 cases.

By the use of the base rates, it was possible to compute the frequency with which a given nosological category selected by one psychiatrist in a pair would be matched by the same diagnosis by the other psychiatrist under conditions of chance. The chance probability for a given nosological category was computed by multiplying the respective base rates for each category for each psychiatrist in the pair. Psychiatrist A, for example, made the diagnosis of schizophrenic reaction 20% of the time in the combined sample, while Psychiatrist B made this diagnosis 18.1%. The chance probability of their both making this diagnosis on the same cases is the product of these two proportions, or 3.6%. The actual number of cases in which they agreed on this diagnosis was 7 of 44 cases examined together, or approximately 16%. The total percentage agreement on all 44 cases which might be expected by chance was obtained by summing the expected percentage agreements for each nosological category. The observed and expected agreements for each pair of psychiatrists are summarized in Table 3. It is evident that the percentage of agreements is highly significant.

The comparison of the degree of agreement for each of the nosological categories is presented in Table 4. (Only categories which were selected at least 10 times are included in this table.) To determine the percentage agreement, the number of selections of the specific category which were concordant was divided by the total number of times that category was selected. It was found that the highest degree of agreement was obtained for the diagnosis of neurotic depressive reaction (63%), followed by anxiety reaction (55%), sociopathic disturbance

* N=Number of times each diagnostic category was selected by a psychiatrist. Since only those categories which were selected at least ten times are included, the diagnoses falling into the other categories are not represented in this table.

(54%), and schizophrenic reaction (53%).

A comparison was also made of the degree of agreement when only the major divisions (psychosis, neurosis, and character disorder) were used to classify the patients. It was found that for this analysis the rate of agreement was 70%.

Another comparison relevant to the problem of diagnostic agreement is the determination of the relationship of the degree of concordance to the degree of certainty (certain, fairly certain, or uncertain) in rendering this diagnosis. Table 5 shows that, when both diagnosticians in a pair indicated that they were certain of their diagnosis, they concurred in their judgments in 81% of the cases. There was a sharp drop in the level of agreement when either diagnostician indicated a lesser degree of certainty. Of the 4 cases which both diagnosticians labeled as "uncertain," there was agreement in only one instance. A comparison of the percentage agreement in the certain-certain category with the percentage agreement in all other categories combined revealed a significant difference ($p < .001$).

The question whether the diagnosticians' appraisals of specific cases may have been closer than indicated by the comparison of their primary diagnoses was explored by

analyzing the degree of concordance when their alternative diagnoses were taken into account.

The N in this analysis is only 51, since the procedure of making an alternate diagnosis was initiated in the latter portion of the study. It was found that, when concordance between a primary diagnosis and an alternate diagnosis or between two alternate diagnoses are given the same weight, the diagnoses were congruent in 43 of the 51 cases (82%). The types of agreement were as follows:

	<i>cases</i>
Primary Diagnosis with Primary Diagnosis :	25
Primary Diagnosis with Alternate Diagnosis :	12
Alternate Diagnosis with Alternate Diagnosis :	6
No agreement :	8
Total :	51

Another pertinent analysis is the comparison of the degree of agreement on the ratings of the depth of depression (D of D). One hundred and forty-eight cases were used in this analysis. It should be pointed out again that these ratings were

TABLE 5
Comparison of Degree of Certainty in Making Diagnoses with Percentage Agreement

	CERTAIN- CERTAIN	CERTAIN- FAIRLY CERT.	CERTAIN- UNCERTAIN	FAIRLY CERT.- FAIRLY CERT.	FAIRLY CERT.- UNCERTAIN	UNCERTAIN- UNCERTAIN

Agree	25	23	3	24	8	1
Percent	81	49	50	50	47	25

not simply estimates of the level of the patient's mood, but were based on quantitative judgments of the severity of 22 specific signs and symptoms characteristic of depression. The final rating of the D of D as none, mild, moderate, or severe was not simply a composite of the individual ratings but involved as well the clinician's judgment of the patient's behavior as a whole. It was found that in 87 cases (58.8%) the psychiatrists placed the patients in the same D of D category, and in 60 cases (40.5%) in adjacent categories. Thus, in 99.3% of the cases, the judgments were no more than one scale point apart.

DISCUSSION

In a previous review article(3), the data of 4 studies(2, 10, 19, 20) were reorganized to facilitate comparison and were found to range in agreement on specific diagnoses from 32% to 42%. The results of the present study indicate that, by using a more stringent experimental design, it is possible to obtain a higher proportion of agreement between diagnosticians than in the more loosely designed studies. The only other study of an *outpatient* population was that reported by Ash(2), which showed a substantially lower degree of agreement on specific diagnoses than the present investigation (32% as compared with 54%). The various studies of *hospitalized* cases are not strictly comparable to the present study because, for the most part, they included "organic" cases, had a higher proportion of psychotics, and included more severely ill patients. In addition, the other studies tended to use broader nosological categories and permitted the second diagnostician in the pair to know the diagnosis made by the first, factors which would tend to inflate agreement. The samples of hospitalized patients which are most similar to our outpatient series in terms of severity of illness and the relative proportions of the diagnostic groupings are the hospitalized naval patients studied by Hunt, *et al.*(10), and Wallinga(20). Their samples are more congruent with an outpatient population since they included a higher proportion of individuals who were hospitalized because of the exigencies of the service and who would ordinarily have been evaluated on an am-

bulatory basis. A cross-study comparison of the concordance rates for the specific diagnoses reveals the following: present study, 54% Schmidt and Fonda, 42%(19); Wallinga, 41%(20); Ash, 32%(2); Hunt, Wittson, and Hunt, 32%(10). These comparisons indicate that the previous studies, while perhaps reflecting the concordance rate in actual practice at various institutions, underestimate the degree of agreement obtainable under more optimal conditions.

Granted that the proportion of agreements can be improved by refining the experimental design, there is still a serious question as to whether the rate of agreement for the refined diagnostic categories is high enough for the purposes of research and treatment. Furthermore, although the degree of agreement was found to be statistically greater than could be expected from random pairing of diagnoses rendered independently by each of the psychiatrists according to his own system of preferences or biases, this does not in itself indicate that the reliability is high enough for research and treatment purposes. It seems apparent that the rate of agreement of 54% for the refined diagnostic categories is not adequate for research. Moreover, it is questionable whether the rate of 70% for the major divisions (neurosis, psychosis, and character disorder) would be considered adequate for research.

An alternative approach for identifying criterion groups is suggested by the results of the comparisons of agreement on the dimension of depth of depression. It was found that, in practically all the cases, the paired ratings were either identical or were at adjacent points on the 4-point scale. By focusing on specific sign-and-symptom clusters and obtaining a measure of these dimensions irrespective of the nosological category, it is possible to divide the patient sample into high and low groups as regards the specific dimension, with confidence that patients at the opposite poles of the continuum (*i.e.*, more than one scale unit apart) would be reliably differentiated by diagnosticians. This technique is based on the "polydimensional" model(13) which does not require that individual syndromes be mutually exclusive, but assumes that more than one of the syndromes or dimen-

sions (e.g., depression, anxiety, paranoid tendencies) may be present in a given patient. This model allows for an estimate of the relative severity of these syndromes, and has served as the basis for a number of techniques which retain the traditional nosological categories but treat them as dimensions of personality (9, 14).

The present study also offers some information regarding the effect of individual differences on the degree of agreement. As shown in Table 2, Psychiatrist D not only had a significantly lower proportion of agreement than Psychiatrist A, but consistently showed a lower rate than the other psychiatrists. Several possibilities are suggested to explain his consistently lower proportion of agreement. One is that he exercised less consistency in his use of the diagnostic procedures and the application of the criteria for the selection of the proper nosological label; his diagnoses thus would show a lower degree of concurrence than would diagnoses rendered by psychiatrists who were more stable in this respect. The degree of consistency thus would be an index of the *reliability* of his diagnoses. Another possibility is that he was less "correct" in his diagnostic appraisals; that is, that his diagnoses had less *validity*. There is no indication as to which factor, lower reliability or lower validity, was responsible for the differences. Since Psychiatrist D had appreciably less experience in psychiatry than the other psychiatrists, as indicated in Table 1, the question could be raised as to whether differences in the degree of experience of the participating psychiatrists might be a factor in lowering the degree of agreement in this and in other studies.

The problem of why psychiatrists differ in their diagnostic judgments was approached in another study by the present authors (21). It was found that, in 37% of the cases of disagreement, inconsistencies or omissions in the interviewing procedure contributed to the lack of agreement. Additional evidence of individual differences is provided by Rosenzweig, *et al.* (18), in their study of the reliability of the mental status examination. They observed that there were no consistent differences among psychiatrists in rating the material elicited by one

of them during a specific interview; but that, when each psychiatrist conducted an interview, he differed from each of the others in the aspects of psychopathology which he elicited. The authors concluded that, while reliability was not significantly influenced by individual bias or by differing capacities to make observations, it was significantly influenced by the individual differences in interviewing techniques.

This evidence of the effects of differences in interviewing technique seems sufficient to warrant further systematic studies of the various methods involved in diagnosis and further attempts to improve and standardize current diagnostic procedures (5, 6). This position is supported by several authors (11, 12, 17) who have viewed with concern the tendency to neglect the concepts of nosology in teaching and practice and plead for increased attention to the orderly description and classification of the mental disorders. As pointed out by Norris (16), a declaration of no confidence in the psychiatric nomenclature can provide a ready justification for avoiding the disciplined investigation involved in making a diagnosis. In this connection, it may be predicted that, if the dissatisfaction with diagnosis increases and the emphasis continues to shift away from coherent observation, description, and classification, the diagnostic procedures may become progressively less reliable. On the other hand, there seems little question that an improvement in diagnostic procedures would advance research and through the expansion of knowledge would ultimately promote therapy.

SUMMARY AND CONCLUSIONS

1. An investigation of the reliability of psychiatric diagnoses was designed to minimize factors that would artificially lower or inflate the rate of concordance. A series of 153 patients were examined independently by paired psychiatrists and diagnoses were made independently according to the standard nomenclature. The degree of agreement (54%) on specific diagnoses was statistically significant ($p < .001$) and was higher than that obtained in other comparable studies.

2. In cases where both diagnosticians indicated they were certain of the diagnosis, the agreement rate (81%) was found to be

significantly higher than in the remaining cases.

3. When the diagnosticians gave both a preferred diagnosis and an alternative diagnosis, it was found that the rate of agreement between either diagnosis offered by one diagnostician and either diagnosis of the other was 82%. This suggested that the diagnosticians may have been closer in their appraisals than indicated by the scoring of only the preferred diagnoses.

4. An additional method of classification consisted of rating the patients on a 4-point scale along a single dimension, *viz.*, the depth of depression. It was found that, when they used this method, the diagnosticians agreed within one scale unit in 99% of the cases.

5. It was suggested that the present system of diagnosis could be improved by focusing greater attention on appropriate training in diagnostic skills, the identification of the defects in current interviewing techniques, and the development of more uniform clinical procedures.

ABSTRACTS

A SEARCH FOR THE AFFECTIVE DETERMINANTS OF CHRONIC URTICARIA

ROBERT J. SHOEMAKER, M.D., MACY I. LEVINE, M.D.,
WILLIAM G. SHIPMAN, Ph.D., AND MARY A. MALLY, M.S.S.¹

Standard operating procedures of psychiatric appraisal, in a multidisciplinary framework, were utilized in the investigation of 40 cases of chronic urticaria. Each patient was seen in 2 to 5 appraisal interviews by the psychiatrist and, in addition, 12 of them entered into psychotherapy with the effect of subjecting initial impressions to extended critical evaluation. Exhaustive physical and laboratory study of each patient by the allergist has failed to produce evidence of physical cause for the disorder. Social studies were conducted by the psychiatric social worker in one or more interviews—when possible a relative was also interviewed. Twenty-six of the patients were given a full battery of psychological tests.

Twenty-four of the patients are female, 16 are male; average age 33. Three females and 1 male are negro; 1 male is Chinese; the remainder are white. There is a marked tendency for the patients to occupy the extremes of ordinal position in their families—13 were the youngest and 14 were the oldest children in relatively large families.

A primary aim of this study was to compare the current cross-sectional view of the patient, while troubled with his chief complaint of hives, with a longitudinal view of his origins, the course of his life, and his characteristic personality defense patterns. Special attention was paid to the childhood milieu in an effort to evaluate the forms of the early and ongoing relationship with parents and siblings. Evaluation of the life setting in which chronic urticaria first occurred has brought out an explanation for

activation of the somatic process. In the search to identify and specify the affects pertinent to the urticarial reaction in these patients, many factors have been considered. The role of anxiety, hostility, guilt, shame, resentment, and depression has been estimated in each case. In a like fashion, evidences of sado-masochism, voyeurism-exhibitionism, and special skin erotism have been considered from the genetic and dynamic standpoints.

DISCUSSION

Estimation of the ego defenses of these patients made clear the effects and operation of activity, acting, or acting-out at various times in their lives. A pattern of failure of activity defenses in a setting of recapitulated childhood dependency conflict has characterized the requisite emotional climate for an episode of urticaria. Statistically, there is a very high incidence of alcoholism or obesity in the past histories of these patients. Descriptively, during the period of evaluation, these 40 patients were separable into 3 groups as far as ego functioning is concerned. One group was designated the "social normal" by virtue of general personality effectiveness and minimal overt anxiety. The second and largest subgroup was characterized by passive-dependency and the third by lessened but persistent acting-out and impulsiveness. No matter how masked by defenses, a common sort of vulnerability was found among them and certain basic conflicts were common to all. Urticaria was found to develop from a frustrating reality situation in which previous personality defenses such as acting-out, compulsivity, sheer physical work, or mere physical activity were no longer appropriate to bind underlying conflict. There was no exception to the persistence of essential and excessive dependent needs

¹ Respectively, Clin. Ass. Prof. of Psychiatry; Clin. Ass. Prof. of Medicine; Staunton Ass. Prof. of Psychology, now Staff Psychologist, Michael Reese Hospital; Chief Psychiatric Social Worker, Staunton Clinic, School of Medicine, University of Pittsburgh.

in these 40 patients.

The body of this paper is devoted to the exposition, centered on the clinical material, of the relation of unconscious conflict to the production of the physical symptom. Characteristically, original intra-family dynamics were recapitulated in a later life situation in which the failure of previously successful personality defenses has resulted in the formation of this particular physical disorder. Parental duplicity was found crucial to the origin of acting-out among these patients. Copious clinical material provided information of a cause and effect nature at a number of levels and theoretical constructions have remained centered upon the patients under consideration. A number of articles in the literature pertinent to the study of urticaria were reviewed and those bearing on the content or conclusions have been included in the bibliography.

SUMMARY AND THEORETICAL CONSIDERATION

Chronic urticaria may be viewed as a regressive, biological attempt to solve an unconscious conflict when more complex psychological modes have become unavailable. As a physiological expression of fear, chronic, recurrent urticaria constitutes an archaic discharge function, an atavistic reaction, that echoes primitive animal defensive reactions to danger. A regressive phenomenon, occurring in a transient setting of the inhibition of defenses adequate to master anxiety, it is postulated that the affective force stems from intense abandonment fear, and infantile companion rage. Solution to the essential abandonment fear and impending panic (threat of annihilation) is found by the displacement of the primary affect to the fear of being hurt (castration anxiety). Thus, essential abandonment fear is avoided by way of a conversion reaction in which a substituted lesser fear is in turn solved by the wheal formation as a physical expression of injury. The wish to hurt and the counterwish to be hurt finds satisfaction in the physical evidence of punishment. The markedly phallic personality organization of the women, together with the decidedly phobic characteristics of the patients as a group, have made the above formulation tenable. This chain of events, with the phantasy of catastrophe

at its beginning, has accomplished a progressive and relatively economical degradation of an initial threat by the formulation of a satisfactory symbolic solution.

CONCLUSIONS

1. Medical study of 40 patients failed to produce evidence of an allergic mechanism or a causative physical agent in the etiology of their chronic urticaria.
2. Chronic urticaria may be viewed as a regressive, physiological expression of unconscious conflict when previously operating mechanisms of defense have become inadequate to bind strong affect. Anxiety is the dominant affect in this disorder.
3. Regression from a pre-dominant action level of tension discharge to an organ level of expression is dynamically crucial to the formation of chronic urticaria.
4. The prime affective force in chronic urticaria stems from a revival of abandonment fear and companion rage, called up in a state of helplessness engendered by a particular set of life circumstances.
5. The conversion process offers the most satisfactory explanation for the physical reaction of chronic urticaria among the patients in this series.

PROLONGED HIGH DOSAGE MEDICATION IN CHRONIC SCHIZOPHRENIA

D. ROSATI, M.D.¹

While there appears to be general agreement that the ataractic drugs, while not curative, are useful, there are still segments of psychiatric thinking which question even this usefulness, suggesting that their value is no more than that of a placebo.

It is our belief that one important source of the confusion and the conflicting reports about the results or the lack of results of ataractic medication, especially in chronic cases, is the extreme variability of dosage and duration of treatment.

Low dosages and shortness of treatment in such a long-term abnormality as schizophrenia cannot but yield negative results, and to expect otherwise is to imply an etiological infectious process or some metabolic deficiency which no one, as yet, has proved.

This assumption is implied in the widespread practice of stopping medication or reducing it to a minimum as soon as the patient's behaviour is stabilized.

Chronic cases are notoriously refractory to remissions as their length of chronicity increases; this has been proved by a series of studies, as the one of the Warren State Hospital in collaboration with the Public Health Service, by the studies of Goldman, Kline, the team of Tuteur, Stiller, *et al.*, even with the use of ataractic drugs.

It would then appear that, in view of such a pessimistic prognosis for chronic schizophrenia, any drug or any method of treatment capable of improving such prognostic outlook could be accepted as proof of the intrinsic worth of the drug or method of treatment. We believe that our report shows such improvement and that its results can be duplicated, provided that dosage and duration of treatment are closely followed.

We consider of paramount importance in the treatment of chronic schizophrenia the following factors:

1. *Adequate high dosage.* High dosages

have been used by many investigators, but with the purpose of controlling acting out and seldom with the long-term therapeutic purpose. Active symptoms can reappear prolonging unduly any treatment; therefore, after the first phase of high dosage to remove symptoms, we keep our patients on high dosages with the purpose of consolidating whatever improvement has occurred. This first stage, lasting about 5 or 6 months, usually consists of medication with 400 mg. of chlorpromazine (Thorazine) q.i.d. to which we add an anti-parkinsonian drug and, whenever depressive features are prominent, imipramine (Tofranil) or tranylcypromine (Parnate). Of late we have resorted to chlorpromazine medication only, sometimes up to 600 mg. q.i.d., whenever acting out is prominent, preferring in other cases where suppression of symptoms is not so important the milder drug thioridazine (Mellaril).

The second stage (therapeutic) is essential to consolidate gains and effects those changes which usually lead to social or full remission. This second stage consists of a change of medication from chlorpromazine to thioridazine or in special cases to trifluoperazine (Stelazine), but reduced by one fourth from the original high dosage, 300 mg. q.i.d. in the case of thioridazine or chlorpromazine and 15 mg. q.i.d. in the case of trifluoperazine. This second stage lasts from a minimum of 6 months in the less chronic (2-3 years of continued hospitalization) to 1 year or even 1½ years for the more chronic and refractory ones. If after 1½ years of this second stage no further improvement occurs we conclude that the case is a decompensated one, to use a fitting medical term, and the prognosis is poor. At the end of this second stage we lower dosage by another fourth; this we consider to be the best maintenance dosage, only in less chronic cases going to dosage of 100 mg. q.i.d. of thioridazine, chlorpromazine or 10 mg. b.i.d. of trifluoperazine.

¹ VA Hospital, Pittsburgh, Pa.

2. *Consistency of dosage.* Fluctuations in dosages, and worse, even short interruptions, we consider to be important factors leading to relapses and chronicity. We withhold medication for one day or two to control some cases of hypotension; in most cases that is sufficient. In cases of persistent hypotension we change the type of drug, never the dosage, unless this be a case of idiosyncrasy.

3. *Medication insight.* We apply this term to the education of the patients ready for discharge, to accept medication indefinitely as part of the process of getting and staying well. We believe that besides the factor of low dosage this lack of consent from the patient is responsible for the high rate of relapses. We include in this education the relatives. To facilitate this consent the medication with thioridazine or trifluoperazine is very important because this drug does not cause slow down and drowsiness, which is, we have learned, the chief reason why patients reject medication after their discharge. During this education period we expand the activities of our patients, especially the socializing activities, and we find that they progress more rapidly and more fully.

The results of such treatment are as follows: Two wards of the continued treatment, having a population of 55 patients, with diagnosis schizophrenia, averaging 35 years in age and 7 years of hospitalization, chronically combative, elopers, suicidal and some lobotomized, were treated. During 1960 and '61 we discharged 26 patients, a social remission rate of 48%, the highest known to us.

Discharge policy was based on complete disappearance of symptoms, change in the pathological pattern of behaviour, ability to hold responsibility of privileges at least for 6 months, and ability to travel alone and adjust to the community.

Of these 26 patients, after the customary 1 year of trial visit, 11 or about 40% have been discharged who are working and are considered to have reached full remission; this is the highest rate known to us, the previous best being 6% reported by the Elgin State Hospital. Most statistics report within 6 months a relapse rate of 20%; we have had only 1 relapse, a rate of 4%.

To be noted is the observation of the follow-up; most patients have continued to improve while on trial visit, 2 social remissions becoming full remissions.

PROGNOSTIC SIGNIFICANCE OF INSIGHT IN SCHIZOPHRENIA

ROBIE T. CHILDERS, JR., M.D.¹

A recent report(1) indicates that chronic schizophrenic patients who lack insight more often require hospitalization than those who recognize their illness, but that once hospitalized they respond to phenothiazines more favorably than those who "accept" their illness. This report relates our experience with newly admitted female schizophrenics and compares the responsiveness to phenothiazines in those with and without insight.

Paranoids lack insight more often and their improvement rate is considerably lower than that of the chronic undifferentiated type. When one compares the improvement

rate within this diagnostic subcategory, however, one finds that "deniers" improve as often as "acceptors." Contrasted to this, 66% of chronic undifferentiated "acceptor" patients improved, and only 27% of the "deniers" improved.

A recent paper(1) discusses "acceptors" and "deniers" in a group of chronic schizophrenic outpatients. It indicates "deniers" are more often hospitalized than "acceptors" but that once in the hospital the "deniers" respond more favorably to treatment with phenothiazines.

Our experience, though limited, would indicate that those who have insight will fare as well, if not better, than those lacking insight.

¹ Richmond State Hospital, Richmond, Ind.

In 82 newly admitted female schizophrenics (the chronic undifferentiated and paranoid segment of 98 patients) who participated in a study of the comparative effectiveness of chlorpromazine and trifluoperazine(2-4), it was found that the "deniers" and "acceptors" responded equally well in the paranoid schizophrenic—i.e., 30% improved in the "acceptor" and 36% improved in the "denier" group. In the chronic undifferentiated group 66% "acceptors" improved compared to a 27% improvement rate in the "deniers."

Insight was scaled as follows: No comment or a denial of any type of illness being associated with their hospitalization; 49% fitted into this category and were considered to have no insight or be "deniers." The remaining 51% acknowledged physical, nervous or emotional illness as the reason

for hospitalization and were considered to possess some insight and fitted into the "acceptor" group. Of the 30 paranoids, 57% had no insight compared to 45% of the 52 chronic undifferentiated patients.

Table 1 classifies the 82 patients into the two diagnostic categories and depicts the relative responsiveness of the "acceptors" and "deniers" to phenothiazine therapy. Table 2 is an abbreviated form of Table 1. $\chi^2=6.49$ $P<0.05$.

TABLE 2

Relative Responsiveness of Acceptors and Deniers to Phenothiazine Therapy

	NUMBER IMPROVED	PERCENT IMPROVED	NUMBER UNIMPROVED	PERCENT UNIMPROVED
Acceptors	22	52%	20	48%
Deniers	12	30%	28	70%
	$\chi^2=6.49$		$p<0.05$	

TABLE 1
Response of Acceptors and Deniers by Diagnostic Subcategory

CHRONIC UNDIFFERENTIATED TYPE—TOTAL 52 PATIENTS					
	NUMBER	PERCENT	NUMBER	PERCENT	
	TOTAL	IM-PROVED	IM-PROVED	UNIM-PROVED	UNIM-PROVED
Acceptors	29	18	66%	11	34%
Deniers	23	6	27%	17	73%
PARANOID TYPE—TOTAL 30 PATIENTS					
Acceptors	13	4	30%	9	70%
Deniers	17	6	36%	11	64%

The above should improve our prognostication, especially in the more frequent chronic undifferentiated schizophrenic.

CLINICAL NOTES

(The Clinical Notes report the findings of the authors and do not necessarily represent the opinion of the Journal.)

EFFECTS OF CHLORPROMAZINE ON BRAIN TISSUE RESPIRATION

JOSEPH WORTIS, M.D.,¹ AND EUGENE JACKIM, M.S.

In the course of study of the possible toxicity of blood serum taken from schizophrenic subjects we chanced upon the unexpected phenomenon of an enhancement of respiratory oxidative activity of the rat brain in the presence of serum of subjects under chlorpromazine medication (1). We therefore undertook to analyze this phenomenon further.

The mechanism of action of the tranquilizing drugs is still largely an unsolved problem. Much of the biochemical work concerning these drugs has centered on their effects on oxidative phosphorylation and binding of serotonin (2, 3, 4). Although this work has been very extensive much of it has been done *in vitro*, and there is still much controversy as to the effects of these drugs on respiration and phosphorylation under clinical conditions.

This report deals with the differential effect of chlorpromazine on brain tissue respiration, with respect to the time interval after injection, and with respect to specific brain divisions.²

White rats ranging from 140-160 grams were injected subcutaneously with 0.5 mg. of chlorpromazine in a 1 mg./ml. saline solution. Control rats were similarly injected with 0.5 mg. of normal saline. After various time intervals ranging from one hour to four days the animals were sacrificed by decapitation. The brains of each drug-treated and control pair were quickly removed and minced. Small aliquots (about 16-30 mg.) of the minced tissue were weighed and placed in a Warburg res-

pirometer flask containing two parts Krebs-Ringer phosphate solution with 200 mg. percent glucose and one part pooled normal human serum. The flasks were then oxygenated and run for tissue oxygen uptake according to standard Warburg procedures (5). Six flasks were prepared from the brain of each rat. After a 2-hour run the oxygen uptake readings were taken and the average oxygen uptake per mg. of tissue for each brain was obtained. In a number of runs, brain homogenates were used instead of minces.

In another study, 30-40 gram white mice were used in a similar manner except that no serum was added to the Warburg vessels. The mice were injected with 0.1 mg. of chlorpromazine and again decapitated after various time intervals. Control mice were injected with saline. The brains were separated into two portions, *viz.*, a cerebral hemisphere portion (including the cerebellum) and a midbrain and stem portion. These parts were then separately minced, weighed, and run in a Warburg apparatus as in the above experiment. The average respiration rates were then compared with those from the control animals.

RESULTS

Chlorpromazine under these experimental conditions appeared to produce a biphasic effect, with respect to elapsed time after administration, on whole brain minces and homogenates. Figure 1 shows the mean of the percent difference between the control and chlorpromazine treated animals, using minced brain. It is seen that there is an initial inhibition of respiration followed by an enhancement. Table I gives the actual experimental values expressed in mm. of oxygen consumed per mg. of tissue for the 2-hour period. Table 2 gives the values

28.5	1.55	1.63	+5
46	1.53	1.61	+5
48	1.50	1.59	+6
Mean	1.54	1.68	+9.1

for similar experiments using the homogenates. The homogenate values are all lower than the mince values, probably due to greater cell disruption. The rather large variations from one run to the next prob-

ably resulted from differences in room temperature and humidity during the time of preparation of the brain samples. By pairing the control simultaneously with the drug treated tissue this artifact is automatically cancelled out, as both samples are subject to the same conditions.

Thus in eight consecutive instances where the animal was sacrificed before 17 hours, an inhibition of brain respiration was found in every case and in 16 trials after 17 hours not a single instance of inhibited brain respiration was found. The basic finding of this reversal of effect thus has a high level

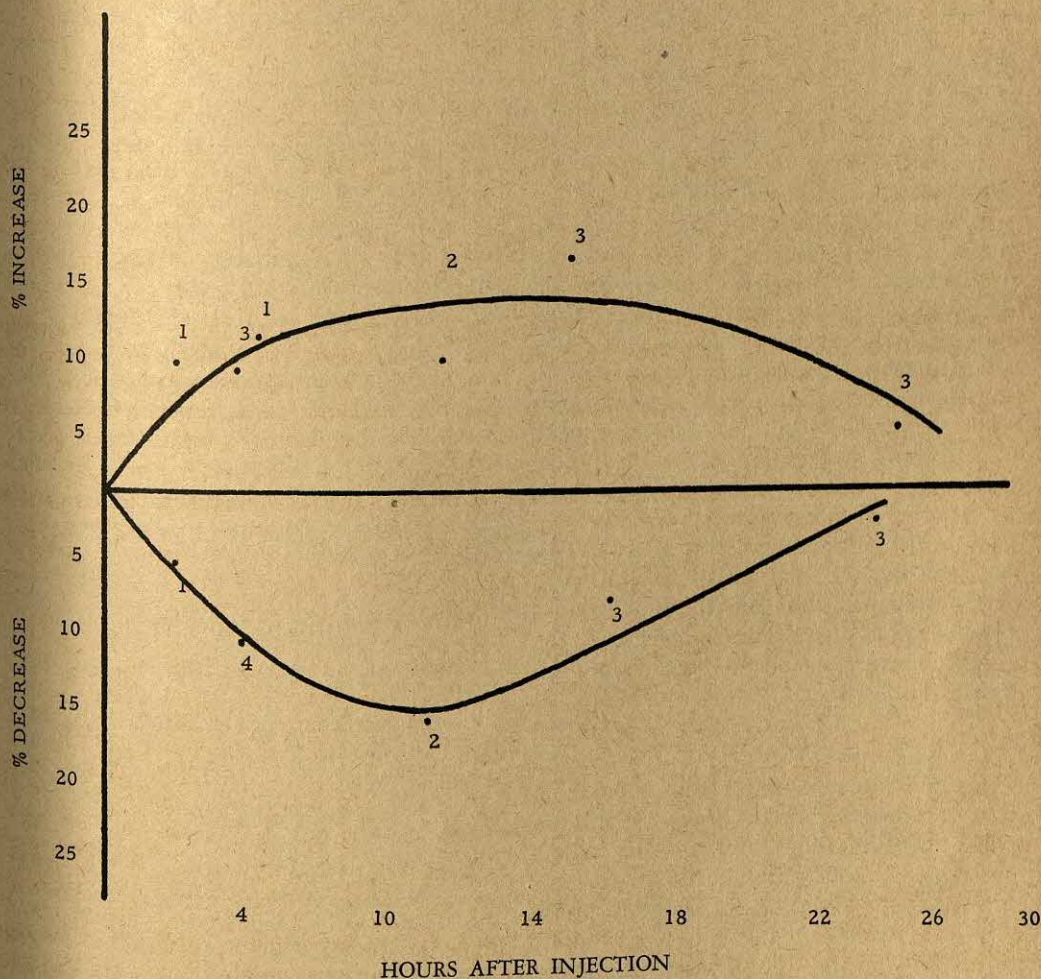

of confidence, with $p < .001$ (sign test).

Figure 2 represents the percentage change in oxygen uptake in the mouse brain hemisphere and brain stem with respect to time after chlorpromazine injection. The diagram shows that there is a pronounced tendency towards an increased hemisphere respiration, while that of the brain stem is usually decreased. Table 3 shows the actual experimental results of this experiment.

DISCUSSION

We do not know if the differential inhibitions and enhancements of brain respi-

FIGURE 2
The Effect of Chlorpromazine on Mouse Brain Stem and Hemisphere Tissue with Respect to Time Interval after Administration

The upper curve represents the hemisphere respiratory enhancement after chlorpromazine treatment, while the lower curve represents the respiratory inhibition on the brain stem after chlorpromazine administration. The numbers above the points on the curve represent the number of mice used to obtain the indicated average value.

ration found in this study reflect functional activity in the intact brain. But these studies strongly suggest the necessity of distinguishing between the immediate and the prolonged effect of these drugs when studying their effects on metabolism. They also demonstrate the pitfalls involved in studying the brain as a single homogeneous organ as some of the biochemical studies have done. A differential biochemical effect with respect to area of the brain affected has also been observed by Mariani and Reda on the phosphatase enzymes(6). This tends to indicate that gross respiration is not the only metabolic activity which shows opposite effects in different parts of the brain in response to chlorpromazine administration.

SUMMARY

This work demonstrates that there is a biphasic effect on brain tissue respiration with respect to time interval after chlorpromazine administration to an intact animal. The first phase, lasting about 16 hours in the rat, reflects an inhibition of respiratory activity while the second, persisting about 4 days, reflects an enhancement of

respiration. It is not clear at this point whether this biphasic effect is due to a peculiarity of metabolic activity or simply represents a different rate of penetration into cortical and subcortical structures.

We have demonstrated that chlorpromazine can induce opposite effects on brain tissue respiration in different parts of the brain. The hemispheres including the cerebellum show an increased respiration while the midbrain and stem show a depression of respiration following chlorpromazine administration.

MASSIVE DOSES OF TRIFLUOPERAZINE IN THE TREATMENT OF COMPULSIVE RITUALS

MILTON ALTSCHULER, M.D.¹

During the course of treatment of a chronic schizophrenic patient with incapacitating rituals of 8 year's duration, it was observed that increasing the dosage of trifluoperazine (Stelazine)² caused a remission of the compulsive symptomatology although the patient's autism and apparently flattened affect remained relatively unchanged. Since the compulsive ritual is found in all forms of psychiatric illness, it was decided to study the efficacy of treating patients exhibiting an incapacitating compulsive ritual with large doses of trifluoperazine.

Twelve patients with these symptoms were selected. All had been coded out as obsessive compulsive neuroses at least once and were classified as follows: 1. Chronic undifferentiated schizophrenia with incapacitating rituals, 4 patients; 2. Chronic undifferentiated schizophrenia with incapacitating rituals and mental retardation, 3; 3. Obsessive-compulsive neuroses, 3; 4. Obsessive-compulsive neuroses with mental retardation and grand-mal seizures, 2.

All patients had previously received somatic treatment, ECT and/or deep insulin coma, various drug regimens plus psychotherapy with little, if any, relief of symptomatology. Each patient was incapacitated by compulsive rituals at the onset of trifluoperazine therapy.

No attempt was made at environmental manipulation or psychotherapy. The only alteration in the patients' lives was the introduction of gradually increasing doses of trifluoperazine up to a maximum of 120 mgm. daily and a concomitant antiparkinson drug. The maintenance dose was determined as that which relieved the patient's symptoms. All patients were followed with monthly CBCs, urinalyses, alkaline phosphatases and BUNs. Patients were followed at intervals of 4-6 weeks in the out-

patient clinic.

Three patients were unable to tolerate the drug owing to development of reversible dystonias in spite of adjunctive antiparkinson drugs. Two patients who had dosages of 60 mgm. daily were unimproved when discharged from the hospital and then refused to take the prescribed medications. Two patients received dosages of 120 mgm. of trifluoperazine for 3 months without any improvement in the ritualistic behavior. Two patients showed marked improvement with complete remission of all ritualistic behavior on dosages of 60-90 mgm. daily. Two patients showed a moderate improvement and were able to function without much difficulty in a free social environment. One patient showed mild improvement and was able to function outside the hospital, but only in her home environment. The patients with the best response were those whose incapacitating rituals were complicated with such schizophrenic symptoms as autism, poor affect response, thought disassociation and delusions. These 5 patients did not show improvement until the dosage was above 40-60 mgm. daily.

The patients responding to the drugs were grouped as follows: 1. Chronic schizophrenia, 2 patients; 2. Chronic schizophrenia with mental retardation, 2; 3. Obsessive-compulsive, 1.

The 5 patients who showed improvement were maintained on the remission dose, varying from 60-90 mgm. daily, for a period of 6 months and then abruptly removed from the active drug with the substitution of an identical placebo. All 5 patients had an exacerbation of their incapacitating rituals within 1 month following the initiation of placebo substitution and responded within 2 months when the active drug was again built up to levels which caused the initial remission of symptoms.

After 10 months no patient showed any abnormality in their blood studies. The only side effects were dystonias noted above; there were no toxic complications.

¹ Resident Psychiatrist, University of Texas, Galveston, Tex.

² Generous supplies of Stelazine were furnished by Smith Kline & French.

SUMMARY

1. Five of twelve patients with severe compulsive rituals showed improvement in symptomatology on high doses of trifluo-

perazine. 2. Blood and urine studies remained stable throughout the study. 3. Minor dystonic side effects were noted that were readily reversible when the drug was decreased or discontinued.

TREATMENT OF POST-TRAUMATIC HEADACHE WITH IMIPRAMINE

GEORGE PAULSON, M.D.¹

The etiology and treatment of post-traumatic headache rests somewhere in the wide borderlands between psychiatry and neurology. In the search for an effective way to treat the chronic pain and chronic complaints of patients with post-traumatic headache, we have employed a double blind study of imipramine (Tofranil)² in 14 patients in the past 20 months. Patients with obvious depressive symptoms or characterologic defects were excluded, as were all patients with abnormal neurologic or electroencephalographic examinations. All patients had had discomfort for over 6 weeks and all related the pain to trauma. Almost all the patients had dizzy spells, irritability, and complaints of memory loss or inability to concentrate. The pain was usually a steady dull frontal or generalized ache, increased by exertion or bending over. The headache was often made worse by sunlight or heat. Several patients objected strenuously to wearing a helmet, usually referred to as a "steel pot," and several patients had maximal tenderness in the local area of trauma.

The patients all received either imipramine 25 mg. t.i.d. or a placebo for at least 4 weeks. Six patients of 15 received the placebo. Six patients were completely, or almost completely, pain free after treatment. Two of the most dramatically im-

proved patients received only placebo.

In such a small series, with solely subjective criteria for improvement, results can hardly have statistical significance. Nevertheless, there is no conspicuous evidence that imipramine adds to the care of non-depressed patients with post-traumatic headache. We have seen 3 patients with depressive symptoms and a severely obsessive personality who had relief from atypical non-traumatic headache after receiving imipramine, and this concurs with successes reported by Webb and Lascelles(1). In a similar fashion post-traumatic headache in association with prominent depressive symptoms may benefit from treatment with antidepressant drugs. Work by Lebourges and Callie(2) would indicate amelioration of neurotic depression-like states in patients who have post-concussion syndromes.

Optimal treatment always depends on accurate diagnosis. Diagnosis of the depressive syndrome, after all, depends on definite symptoms and signs. If these signs are present in a patient with post-traumatic headaches, therapy with an antidepressant drug seems logical. In patients with post-traumatic headache who do not appear to have depression, imipramine is of no conspicuous benefit.

HIGH DOSAGES OF MEPROBAMATE IN CHRONIC SCHIZOPHRENIA¹

LAURENCE H. SNOW, M.D., KARL RICKELS, M.D., AND
HAROLD H. MORRIS, M.D.²

In the dose range usually employed (1.6-3.2 gm./day) meprobamate has repeatedly been found ineffective in ameliorating the symptoms of chronic schizophrenia. With phenothiazines, the dose range for effective treatment of psychotic patients is much higher than that used for non-psychotic patients.

Questioning whether this would be true for meprobamate, we placed 17 chronic schizophrenic patients from our seemingly drug refractory cases on relatively high doses of this agent. They received a daily dose of 8 gm. meprobamate for 5 days, then 3.2 gm. on the sixth day, 1.6 gm. the seventh day, and then no drug at all. These patients were in an active treatment unit which emphasized milieu therapy and their activity was in no way curtailed, although they were observed by the nursing and attendant staff. Blood pressure was taken twice daily, and any unusual behavior was reported immediately to the study doctors. On the basis of previous experience with meprobamate, we expected that its primary side-effect would be somnolence, but we had no other indication as to what meprobamate in this dosage might produce. The following results were noted:

1. Meprobamate produced no significant hypotensive effects in any of the patients. Diastolic readings (basal) were always above 60.

2. There were no withdrawal reactions.

3. The somnolent side-effect of meprobamate varied quite widely. At no time was this dose sufficient to prevent the patient from being aroused, although several patients became quite drowsy.

4. When drowsiness occurred it took place within the first 24 hours, and wore

off after 72 hours. A patient who was not somnolent at the end of 24 hours did not become so later.

5. While those who were the most somnolent seemed to exhibit the greatest therapeutic effects from the drug, the opposite did not also hold true. The size of the sample, however, precludes any significant correlation of somnolence and drug efficacy.

At the end of our study the patients were returned to their doctors and treated according to normal hospital routine. After six weeks, 6 of the 17 meprobamate patients had returned to the community. This is encouraging, particularly for a drug-refractory chronic schizophrenic population, but the size of the group makes adequate statistical treatment impossible.

Before, during, and after meprobamate, each patient was given a self-rating scale (Clyde Mood Scale). The results showed that, under meprobamate therapy, the patients tended to show increased friendliness and energetic capabilities. There was no apparent change in the categories of depression, aggression or jitteriness. A further interesting, though not statistically significant, result was that in some of the patients an increase in recall of previously threatening childhood memories was noted, and abreactive material heretofore withheld was now volunteered, indicating that meprobamate may also be of use as an adjunct to psychotherapy in psychotics.

SUMMARY

1. Meprobamate in high dosage seems to be of value in the treatment of some chronic schizophrenic patients. If it is, it will exert its clinical effects in a relatively short time.

2. High dosage meprobamate seems efficacious in the facilitation of abreactive recall, even when the drug alone is not sufficient to bring about a clinical change.

3. The absence of side-effects other than

¹ Work carried out at the Mercy Douglass Hospital, Philadelphia, Pa.

² Respectively, Instructor, Assistant Professor, Associate Professor, Dept. of Psychiatry, University of Pennsylvania.

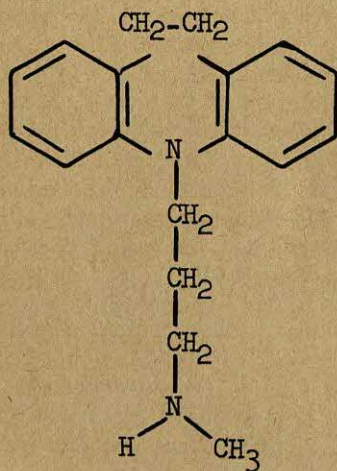

transient somnolence makes meprobamate a relatively easy drug to use in a controlled inpatient setting.

4. Further studies seem indicated to evaluate adequately large dosage meprobamate therapy in schizophrenia.

PRELIMINARY INVESTIGATION OF DESMETHYLIMIPRAMINE (G 35020)¹

JANE E. OLTMAN, M.D., AND SAMUEL FRIEDMAN, M.D.²

This is a report of our experiences with desmethylinipramine in the treatment of depressive states. This compound is a mono-methyl analogue of Tofrānil. It differs from imipramine only in the absence of one of the two N-methyl groups and has the following chemical structure:

DESMETHYLIMIPRAMINE

It is described by the manufacturer as a potent, fast-acting antidepressant agent.

The drug was administered to 50 female patients suffering from acute or recurrent depressive illnesses. They ranged in age from 18 to 82 as follows: under 31—3; 31 to 40—5; 41 to 50—12; 51 to 60—7; 61 to 70—16; 71 to 80—5; 81 and over—2. It would appear that the group was slightly older, on the average, than the subjects we have previously treated with Tofrānil and Elavil. Diagnostic classification is indicated in Table 1. There appeared to be a somewhat greater proportion of manic-depressive psychoses and somewhat fewer neurotic depressive reactions than in the previously studied groups. Dosage was usually initiated at a level of 25 mg. t.i.d., and was increased to 50 mg. t.i.d., as necessary. Maximum dosage prescribed was 200 mg. daily.

As in previous studies, results were designated as satisfactory (A level) in patients

¹ Generous supplies of G 35020 (Desipramine) were furnished by Geigy Pharmaceuticals.

who achieved a remission or much improved status, or as unsatisfactory (B level) in those who failed to improve or exhibited partial improvement only. As indicated in Table 1, 70% of the group exhibited an A level of improvement. Thus the final overall results were essentially identical with those obtained with previous antidepressant drugs, and were in the range of 70% to 75% successful results which, we have indicated (1), may be expected from effective antidepressant agents.

A few comments concerning the progress of patients during the course of treatment with desmethylinipramine are pertinent. Although in most instances, the drug appeared to exert its initial effect within the expected 7 to 10 days, with progressive improvement thereafter, there were 11 cases in which the initial phase of improvement was followed, usually at about the 4th week, by some degree of relapse, or by an extended plateau or levelling-off of improvement. Eight of these patients progressed finally to an ultimately satisfactory result, while 3 failed to respond further. Thus, the ultimate time factor for optimal improvement was, on the average, somewhat delayed, as compared with Tofrānil. It may be noted, on the other hand, that the drug produced a satisfactory response in several severely ill patients who had been refractory to other medications.

Complications or side effects were minimal, as follows : mild perspiration—7 ; dry-

ness of mouth—2 ; drowsiness—5 ; dizziness—3 ; and slight agitation—1. The degree of all of these side effects was very slight ; they usually disappeared after the first week or two of treatment. Drowsiness was apparently a subjective experience only, as somnolence was not observed clinically. Laboratory data remained within normal limits.

Again it may be noted that best results are obtained in the group of "psychotic depressive reactions." Thus, 34 of 39 patients (87%) in this category treated with 1 of 4 antidepressant agents achieved an A level of improvement.

It may be concluded, therefore, that desmethylinipramine is an effective antidepressant agent with minimal side effects. Certain reservations are to be recorded in view of a tendency toward the appearance in some patients, of a relapse or plateau in progress at about the 4th week of treatment. There suggests itself the possibility of combining this drug with small doses of imipramine, thereby utilizing the advantages of each. The drug appears worthy of further study in the ever increasing area of antidepressant agents.

CASE REPORTS

SEVERE BRAIN SYNDROME FOLLOWING PHENELZINE¹ OVERDOSAGE

ALAN C. RAINE, M.D., AND SAMUEL F. THOMAS, M.D.²

Because of the widespread use of phenelzine (Nardil) for depressed patients, the possibility of suicidal overdosage is an ever present danger. Since treatment of the major central nervous system alterations in these cases is somewhat specific(1), it is felt that the following case with closely followed neurological changes well illustrates the suggested management.

A 20-year-old white female had a history of chronic depressive episodes for 2 years; no previous mental hospitalizations. She had been taking phenelzine for 3 months.

Approximately 30 hours before admission, the patient ingested 50 tablets of Nardil (750 mgms.). No other medication was taken. No effects were noted for 10 hours, when she gradually developed increasing weakness, lethargy, dizziness, and impaired gait, and was finally brought to the emergency room. Her blood pressure was 120/60; pulse 80 and regular; respirations 15 and regular. Pupils were slightly dilated and reacted sluggishly to light. Fundi were normal. Corneal reflexes were equal and active, and there was bilateral ptosis. Nystagmus was seen in the directions of lateral gaze. She had general hyperreflexia, transient left patellar clonus, sustained right patellar clonus, and a questionable Babinski reflex on the right. There were intermittent contractions of the jaw, and restless movements of the lower extremities.

She was admitted to the ward, and given Dilantin 100 mgms., and hydrated with 1500 cc. of 5%D/1/4NS. Over the next 2 hours, her restlessness increased to extreme writhing movements of the torso. At this time, about 33 hours following drug ingestion, she was given Thorazine 50 mgms. intramuscularly, with noticeable relief of restlessness after one-half hour. Shortly thereafter, she had a grand mal seizure, and was intermittently comatose with absent corneal and pupillary reflexes for about 2 hours.

Then, approximately 37 hours following drug ingestion, she awoke and was oriented. There were twisting dystonic movements with some waxy flexibility, and frequent periods of spontaneous clonic extensor jerking of the lower extremities. Visual field and fundi were normal. The lids hung down in a bilateral ptosis, and she tilted her head back in order to see what was directly in front of her. The left direct corneal reflex was greatly diminished. Deep reflexes were increased in upper and lower extremities, more so on the left, with plantar flexion and a strongly active sign of Rossolimo. Strength and sensation were normal. There was no finger-to-nose, nor heel-to-knee ataxia. The airway and movements of breathing were entirely normal.

Chemistries drawn shortly thereafter revealed: cephalin flocculation 2 plus; bilirubin 0.6 mg.; SGOT: 12; CBC: normal; urinalysis: normal. Improvement continued, and she was placed on Sparine 25 mg. q.i.d. and p.r.n. for severe restlessness. The following day an EEG revealed generalized abnormality with frequent slow wave runs and a temporal amplitude asymmetry.

From the second hospital day on, there was gradual improvement; the cephalin flocculation and EEG becoming normal by the ninth day. The only remaining neurological abnormality was a slight increase of the right ankle jerk.

It is possible that the toxicity of this drug results from the accumulation of serotonin and adrenergic substances in the brain, causing a hyperadrenergic response. In addition, a sympatholytic response may be present, explaining the frequent occurrence of hypotension(2). Because of this, adrenergic agents for the support of possible hypotension are contraindicated. In addition, the use of barbiturates for the convulsive manifestations is also contraindicated since the monoamine-oxidase inhibiting drugs potentiate barbiturates(3).

Supportive treatment is therefore the treatment of choice, and may be all that is

¹ Phenelzine dihydrogen sulfate.

² Dept. of Psychiatry, St. Luke's Hospital, New York City, N. Y.

necessary with the addition of phenothiazines if required (4). With supportive therapy alone, 1 case of overdosage was noted to recover from hyperreflexia in 3 days after a total dosage greater than that taken by our patient (4).

In summary, the patient developed profound central nervous system depression with acute changes and prolonged residue following a dose of 14 mg./kg. of Nardil, requiring over 10 days for full recovery. Therapy was supportive with emphasis on IV hydration acutely. In addition, pheno-

thiazine therapy, including parenteral administration acutely, and oral medication subsequently were used with good results.

FATAL BONE-MARROW APLASIA COMPLICATING PROCHLORPERAZINE THERAPY

K. BHASKARAN, M.D., P. SUBRAHMANYAN, M.B.B.S.,
AND D. SATYA NAND, D.C.H.¹

In spite of the extensive use of prochlorperazine (Compazine) in the treatment of a variety of psychiatric syndromes, report of only one case of complicating blood dyscrasia has come to the author's notice.² The case reported below is of importance for the following reasons: 1. The patient developed aplasia of the bone-marrow as a complication associated with prochlorperazine therapy. The aplasia was evidenced clinically by peripheral blood-picture of anaemia, leucopenia, thrombocytopenia, prolonged bleeding and coagulation times and symptoms of irregular pyrexia, tiredness, and bleeding per rectum. The diagnosis was confirmed by examination of the sternal bone-marrow. 2. The complication was resistant to energetic treatment, which included repeated blood transfusions, and it ultimately proved fatal. 3. The patient had had prolonged treatment with chlorpromazine previously without any complicating blood dyscrasias.

J.T. was a 42-year-old woman admitted to hospital at the age of 13 with the complaints of restlessness, destructiveness, inability to concentrate, inability to look after herself, etc.,

all coming on after an attack of prolonged pyrexia when she was 9 years old. She was diagnosed as a case of post-encephalitic behaviour disorder, and during her long stay in the hospital she had had all the available treatments without significant improvement. The treatments included: chlorpromazine for 168 days with a maximum dose of 225 mgms./day, reserpine by intramuscular injection for 36 days with a maximum dose of 3 mgms./day and orally for 102 days with a maximum dose of 3 mgms./day. These treatments were not associated with any evidence of liver damage or blood dyscrasias. Her W.B.C. count had often reached figures of between 4000 to 5000 per c.mm. during chlorpromazine therapy, but it was possible to continue the treatment without any untoward symptoms, attributable to leucopenia.

Because she continued to be noisy, combative, destructive and uncooperative, she was started on prochlorperazine, after liver function tests, and total and differential W.B.C. counts showed normal limits: Total plasma proteins — 7.8 gms., thymol turbidity — 1, thymol flocculation — 1, Van den bergh test — negative, total W.B.C. count — 8100/c.mm., polymorphs — 65%, lymphocytes — 30%, monocytes — nil, eosinophiles — 5%.

Blood pressure was 110/70 mm. Hg and E.S.R. 3 mm. in 1 hour.

Prochlorperazine was given orally in doses of 25 mgms. b.i.d. and after 3 days the dose was raised to 25 mgms. t.i.d. The patient tolerated this dose well and appeared to be a

¹ Hospital for Mental Diseases, P.O. Kanke : Ranchi, Bihar, India.

² Stemetil in Psychiatry. Dagenham : May & Baker, 1951.

little quieter and more manageable after 17 days of treatment. Liver function tests were done regularly at 2-week intervals with normal findings. Her W.B.C. count had however come down to 5700/c.mm. with polymorphs 54% at the end of 3 weeks' treatment. The dose of prochlorperazine was reduced to 25 mgms. b.i.d. and so continued for another 46 days without any significant unpleasant symptoms or side-effects. W.B.C. count at weekly intervals varied from 6500/c.mm. to 4800/c.mm. with polymorphs ranging from 55% to 43%. On the 64th day of treatment the patient complained of feeling giddy and tired. The drug was discontinued and she was transferred to the infirmary. She developed, within the next 24 hours, pyrexia of an intermittent type, and bleeding per rectum. W.B.C. count at this time was 3200/c.mm. with polymorphs — 34%, lymphocytes — 64%, monocytes — 0%, and eosinophiles — 2%; R.B.C. count — 2.8 millions/c.mm.; E.S.R. — 73.5 mm. in 1 hour. Stool examination revealed R.B.C.'s in fair numbers, pus cells and macrophages in good numbers. There were no ova or cysts seen.

The patient was started on: crystalline penicillin — 400,000 units 3 hrly., Achromycin — 250 mgms. 4 hrly., vit. C. — 500 mgms. I.V. along with 100 cc. of 25% glucose t.i.d., vit. B. complex — 2 cc. I.M. daily.

The pyrexia and bleeding per rectum continued. W.B.C. count and other counts done 1 week after the development of physical symptoms revealed a total W.B.C. count of

750/c.mm. with polymorphs — 64%, lymphocytes — 32%, monocytes — 2%, eosinophiles — 2%; R.B.C. 2.4 millions/c.mm. Hb 6 grammes percent; platelet count 48,200/c.mm.; bleeding time 20 sec.

The patient was given 450 cc. whole blood and the massive antibiotic therapy was continued. Though the bleeding per rectum stopped temporarily, the pyrexia continued and there was no significant elevation in the W.B.C. and R.B.C. counts and the level of Hb.

A week after the first blood transfusion the patient started bleeding per rectum again and the various blood counts then showed no significant improvement. W.B.C. count was 650/c.mm. with polymorphs — 59%, lymphocytes — 37%, monocytes — 3%, eosinophiles — 1%; R.B.C. count was 2.2 millions/c.mm. with Hb: 5.4 grammes percent. Coagulation time 4.55 minutes and bleeding time 58 secs.

Examination of the sternal bone-marrow revealed complete absence of segmented granulocytes with myeloblasts predominating. There were very few myelocytes and eosinophiles were absent. Erythrocytic precursors were present though in reduced numbers.

The patient was given another 450 cc. of whole blood but her condition deteriorated rapidly and she died on the 26th day after development of the symptoms of pyrexia, bleeding, *etc.*, attributable to the bone-marrow aplasia.

FOUR DEATHS ASSOCIATED WITH CHLORPROMAZINE

ROBIE T. CHILDERS, JR., M.D.¹

Since the introduction of chlorpromazine (Thorazine) there have been innumerable articles attesting its efficacy and necessity in small and large dosages (1, 2) over both brief and long periods of time. Agranulocytosis with death is the main reported toxicity (1, 3). This report lists four deaths occurring on our female service during chlorpromazine administration. The bulk of clinical, laboratory, and autopsy data point toward chlorpromazine being the most likely causative agent. Three deaths occurred during acute intensive treatment of approximately 400 patients with chlorpromazine.

It is not the purpose of this report to impugn or unduly incriminate a highly useful drug but merely to re-alert us to the possibility of serious reactions occurring during chlorpromazine (and other related compounds) administration.

The mortality rate for ECT is about .1%. With up to 5 times the mortality rate occurring with chlorpromazine we should consider it with the same respect accorded to ECT.

With the introduction of most phenothiazines claims as to their efficacy and freedom from toxicity are made which may, in view of the paucity of evaluations, be premature.

It might be well if we recall that we are

¹ Richmond State Hospital, Richmond, Ind.

still learning about our first phenothiazine—its effectiveness, side effects and toxicity. Chlorpromazine still remains the model with which new drugs are compared.

One case, "Hyperpyrexia, Coma, and Death During Chlorpromazine Therapy," has been reported(4). Only the gross aspects of another case can be given due to inaccessibility of records. This patient was a female schizophrenic hospitalized some 10 years. She had received 200 mg. of chlorpromazine over a period of months. She swallowed a bolus of food and died of asphyxiation.

At that time we were not acquainted with the fact that the phenothiazines not infrequently interfere with the process of smooth deglutition. Since then we have encountered several cases where manual removal of a bolus prevented serious consequences.

The third case is a 68-year-old manic-depressive. She was placed on chlorpromazine 100 mg. q.i.d. which decreased her psychomotor rate, but she then developed a feeling of hopelessness on the 6th hospital day. Imipramine 25 mg. t.i.d. was started. She became more depressed and ECT was begun on the 12th hospital day at which time she was first noted to be icteric. Medications were discontinued. ECT was continued, resulting in some improvement, but her eating habits remained poor, necessitating tube feeding. She failed to make the expected progress physically and mentally, and her condition worsened the 36th day; she lapsed into hepatic coma and expired 40 days after hospitalization. As is known, most jaundice associated with chlorpromazine is quite innocuous. Why this case followed a different course is not known.

The fourth case is a 39-year-old schizophren-

ic admitted to the hospital 8 years previously. She received 800 mg. chlorpromazine daily with beginning improvement, but after 28 days of medication she developed a fecal impaction which progressed to intestinal obstruction that failed to respond to conservative measures. She underwent surgery, but died on the second post-operative day. We have recently encountered a similar case of intestinal obstruction also requiring surgery, but happily this case recovered.

We have been aware of the problem of stubborn obstipation and impaction for several years. In view of the rather marked and frequent atony of the bowel we must utilize various measures to prevent serious reactions.

SUMMARY

Four deaths associated and presumably linked with the administration of chlorpromazine is presented. Although the phenothiazines, which have so changed the outlook for psychiatric patients, can usually be administered with only the occurrence of minor side effects, we must always be alert to the possibility of serious side effects. Early recognition and proper treatment should materially reduce the mortality.

HISTORICAL NOTES

JOHN HASLAM ON EARLY INFANTILE AUTISM

GEORGE E. VAILLANT, M.D.¹

Both Bradley(1) and Goldfarb and Dorsen(2) have compiled extensive bibliographies on childhood schizophrenia. Their reviews suggest that not until the first decade of this century when Raecke, de Sanctis, and Heller reported children with catatonia, dementia praecocissima, and dementia infantilis, respectively, was schizophrenia in childhood unequivocally observed. Bradley cites Friedreich in 1834 and Goldfarb credits Rush in 1812 as the first authors to acknowledge even *psychosis* in childhood.

However, in an 1809 textbook, *Observations on Madness and Melancholy*(3), John Haslam observed a patient who in many ways fitted our current concepts of childhood schizophrenia. Haslam, "apothecary to Bethlehem Hospital" and author of the first clinicopathological description of general paresis, recounted the case of a 5-year-old boy admitted in 1799 to Bethlem Asylum. At 1 the child had a severe case of measles. When he was 2, his mother noted that he was "more lively than usual," and more difficult to control. He did not walk until he was 2½ and did not say a word until he was 4. At the hospital, when separated from his mother, he wept only briefly. He was "constantly in action"; and "in a short time he acquired a striking talent for mimicry."

On physical examination his health was good. Although no evidence of neurologic deficit was mentioned, "he appeared to have very incorrect ideas of distances; he would frequently stretch out his hand to grasp objects considerably beyond his reach." Such an observation comes close to describing what today would be regarded as a defec-

tive awareness of ego boundaries or of body image.

Haslam goes on: "To watch other boys . . . gave him great satisfaction but he never joined them nor did he ever become attached to any one of them." He played in an absorbed, isolated fashion with toy soldiers, "retained several tunes and was able to whistle them very correctly," but he would not be taught to read. "Although he was acquainted with the names of many things and also with expressions which characterize passion, he applied them in an insulated way." Thus, Haslam described "splitting" of affect a century before Bleuler. Finally, Haslam completes his description of the child's autistic behaviour by remarking that the patient never used the first person singular but was "always speaking of himself in the 3rd person."

A postencephalitic syndrome cannot be ruled out, but Haslam's clinical report contains 17 of 30 possible items in Polan and Spencer's(4) check list of early infantile autism—even to the point of presenting the mother as a careful historian. In some respects, John Haslam's case appears to have anticipated more closely the observations of Kanner and Bender than any other report over the intervening 140 years.

COMMENTS

THE NEW YORK PLAN

Considerable interest has been expressed in the master plan of the New York State Department of Mental Hygiene recommended by Governor Rockefeller in a special message to the Legislature. The master plan outlines in considerable detail the aims and policies of the Department for the next few years. It was devised to establish a working pattern for the orderly achievement of goals set up for the care of the mentally ill and mentally retarded.

Within the framework of this plan, priorities will be established every year as to what should be done and what appropriations should be requested. The basic focus of the plan consists of 1. The intensification of modern treatment methods; 2. Expanded and intensified research; and 3. Development of coordinated community services.

The intensification of modern treatment methods is based on experience gained on the treatment service for newly-admitted patients in New York State hospitals. These services were re-organized in 1956 to provide for the concentrated application of new therapies together with refinement and intensification of existing therapies. Each service has demonstrated clearly that intensive treatment of newly admitted patients can reduce the length of the patient's hospitalization and by discharging more patients earlier it is possible to reduce the hospital census.

Every state hospital, of course, in addition to the newly admitted patients, contains a large number of chronic patients. In New York State hospitals there are about 30,000 patients requiring long term care who have not responded to treatment. Many of these patients were admitted prior to the initiation of the new drug treatments. Others, while exposed upon admission to some of the new treatment methods, did not respond favorably. During the recent years six experimental treatment units have been operating in the state hospital system to retreat these patients. Results indicate that with intensive retreatment as many as

10% of these patients may improve sufficiently to return to their families. Of course, we do not know how permanent these improvements will be. Nevertheless, we feel that the complete pessimism which has long prevailed regarding treatment results with this group of patients is unwarranted. The retreatment of chronic patients offers sufficient hope to be an important aspect of hospital programs.

There has been much discussion regarding the relative merits of large or small state hospitals. Recognizing the therapeutic advantages of the small treatment unit and the economic advantage of the large physical plant, we believe that our large hospitals in New York could perform quite effectively if we were to decentralize the large hospital complexes into smaller units which are therapeutically self-contained but which can take advantage of the common services such as utilities, housekeeping and maintenance that can best be provided centrally. This program is working well in its pilot stages at Pilgrim State Hospital and Hudson River State Hospital where each smaller unit relates directly to the segment of the community which it services. The Department of Mental Hygiene is planning the future extension of this program in gradual stages to each of the larger state hospital complexes.

Another feature of the master plan is the provision of specialized therapeutic services for patients with special problems. These would include mentally ill and emotionally disturbed children and adolescents, the mentally ill blind, and the mentally ill deaf. Special children's units have been established in nine state hospitals to provide early treatment for children with severe emotional disorders and serious behavior problems. Ultimately, the department aims to have a division for this type of patient in every state hospital. A special unit for emotionally disturbed blind children will be organized, and two units for the mentally ill deaf, one in an upstate and one in a

downstate hospital.

In the central office the Department of Mental Hygiene is also organizing a special bureau for alcoholism and another for narcotic addiction. Special pilot treatment units for alcoholism have been established recently at Central Islip State Hospital and Rochester State Hospital. Special narcotic treatment units have been opened at Manhattan State Hospital, Central Islip State Hospital, and Utica State Hospital. These pilot treatment programs for alcoholism and narcotic addiction, if successful, will be expanded to other hospitals, provided a need is demonstrated.

Considerable attention will be paid to improved living conditions in the state institutions. New treatments can be successful only if linked with such improvements. Comfortable and dignified living conditions are not only therapeutic, but reflect a proper concern and respect for the individual patient. On a continuing basis this means a more plentiful and varied diet, improved housekeeping services, and less crowded facilities. The executive budget for the year 1962-1963 includes funds for improvement in living standards in the state hospitals and schools.

The program reflects broad concern for the mentally retarded with emphasis on improving and expanding the state schools and encouraging the development of coordinated community facilities. Significant progress has been made in the last eighteen months toward relieving population pressures in the state schools through the acquisition of several facilities formerly used for other purposes. These acquisitions, which now serve as auxiliaries for existing schools, include the Sampson Air Force Base Hospital, the J. N. Adam Memorial Hospital, the former veterans rest camp at Mt. McGregor, and Gouverneur Hospital (recently leased from New York City). A new school at West Seneca will open this year and three additional schools will be built at Mt. McGregor, in Huntington on Long Island, and in Brooklyn.

Better care for the severely retarded is another objective considerably furthered recently when the number of persons ministering to total care patients under ten years of age was doubled. Similar increases in staff

will now be provided to improve the care of patients over ten years of age who require constant attention. The budget also provides funds for a strengthened and expanded office of mental retardation in the Department of Mental Hygiene.

A major element in the mental health plan is expanded research. One of the new facilities projected is an Institute for Research in Mental Retardation. An institute for narcotic addiction and an institute for basic pharmacological research will be established at Manhattan State Hospital. New research centers will be organized in the Bronx State Hospital now close to completion and in other new institutions.

Obviously no improvements are possible in any treatment program without adequately trained personnel. The department is deeply concerned with training and recruitment of personnel for the care of the mentally ill and the mentally retarded, as well as provision for proper staffing. In conjunction with the Division of the Budget and the Department of Civil Service, the Department of Mental Hygiene will undertake a comprehensive study of the staffing needs in each institution in order to obtain a sound basis for establishing staffing patterns for future years.

A comprehensive state program for mental health can be effective only if mental health services in the community are strong and are operated in coordination with the services provided by the state. Community clinics and psychiatric units in general hospitals must be extended and enlarged to form a network of accessible facilities serving the community. Moreover, with proper relationship to community psychiatric clinics, nursing homes, homes for the aged, day hospitals, sheltered workshops, and similar community facilities are appropriate places for the care of persons with mild mental symptoms. Development of such integrated services will keep in the community many mildly ill persons who would otherwise have to be hospitalized. The department is particularly interested in developing through the community mental health boards more treatment clinics for prehospital and posthospital care. With such facilities available many patients with more serious disorders would not need to

be hospitalized at all, or would require only short term hospitalization with subsequent treatment in the community. This does not mean, of course, that hospitals for the treatment of mental diseases are obsolete or will become obsolete in the foreseeable future.

The master plan looks toward removal of the existing *per capita* ceiling on state reimbursement for local psychiatric services and immediate implementation was recommended by the department. For budgetary reasons, however, removal of the ceiling was not possible this year, but the *per capita* maximum of reimbursement for community mental health expenditures was raised from \$1.20 to \$1.40. It is Governor Rockefeller's intention to appoint a committee of experienced individuals from outside the state government to study the whole problem of fiscal responsibility for state and local mental health services.

Any new progressive plan for the care and treatment of the mentally ill and the mentally retarded should provide for a thorough review of the laws pertaining to them. Many of the laws, especially those relating to mental hospitals, are geared not to today's needs, not to hospitals for treatment and rehabilitation, but to the practices of over a century ago when the "insane asylum" was used as a fortress for society's protection. Many complex and anachronistic provisions frequently work to the detriment of mentally ill persons who are in need of the modern treatment which

mental hospitals now provide. It has been recognized that the laws relating to admissions are in need of comprehensive revision to reflect the great advances in treatment methods and social attitudes which have changed the mental hospital from a place of incarceration to a place of treatment. At the same time, effective safeguards of due process must be incorporated to protect basic individual rights and liberties. A comprehensive study of admission procedures has been undertaken by a special committee sponsored by the Association of the Bar of the City of New York in cooperation with Cornell Law School. This special committee has been working closely with the Department of Mental Hygiene. A bill based on the findings of this committee and providing for much-needed legal reforms in this field has been submitted to the Legislature for study. In a future editorial we may describe the provisions of this bill.

The New York plan, outlined here only in its essential elements without reference to detail, is a delineation of broad purpose reflecting current concepts and philosophies of care and treatment. For administrative purposes it is projected over a five-year span and gradual implementation is expected. Basic to its realization, however, is full provision for flexibility and adaptation to whatever advances, whatever changes, tomorrow may bring.

P. H. H.

EDUCATION

Man, unlike other animals, from the beginning of time has been driven by the "how" and the "why," yearning to achieve greater moral, aesthetic, and scientific clarity. From this uncomfortable impulse, the most painful penalty for the theft of the apple, has sprung intellectual progress. The teacher of almost any important branch of learning who is not interested in the exploration of new ideas or understanding is as out of place in a university as a prohibitionist in a winecellar.

—HANS ZINN SER
(As I Remember Him)

NEWS AND NOTES

A.M.A. FIRST AID MANUAL.—This compact soft-bound 48-page booklet is profitable reading, for anyone may unexpectedly find himself in an emergency situation where skilled professional help is not immediately available.

Here are listed accidents, injuries and conditions requiring prompt attention, hemorrhage, arrested breathing, shock, poisoning, burns, unconsciousness, heat stroke, fractures, mental disturbances, radiation, emergency childbirth, *etc.*

Instructions are clear, with things listed under DO and under DON'T, with other special directions.

There is also a list of first-aid supplies, and an index of emergencies and procedures.

The Manual may be had from the American Medical Association, 535 N. Dearborn St., Chicago 10, at 15 cents per copy.

ACADEMY OF PSYCHOSOMATIC MEDICINE MEETING.—The ninth annual meeting of the Academy will be held in Minneapolis, November 1-3, 1962 at the newly remodeled Radigan Hotel. The program will be suited to the needs of practicing physicians in all branches of medicine since few illnesses are devoid of psychosomatic complications. There will be a distinguished panel of speakers and numerous interesting extra-curricular features are planned.

DR. IRENE MCCAIN MCFARLAND.—Dr. McFarland, president of the North Carolina Mental Health Association, died in her sleep at her home in Wilson, N. C., July 4, 1962. She was only 38 at the time of her death and was going about her professional and social duties as usual the preceding day.

Dr. McFarland received her A.B. degree from the University of North Carolina and her M.D. from the University of Pennsylvania. Following her intern years she devoted herself to mental health work. She organized and was the first president of the Wilson County (N. C.) Mental Health Association, likewise the director of North

Carolina's first aftercare clinic, a position she held at the time of her death.

Dr. McFarland had served on the staff of the Dorothea Dix Hospital, Raleigh, and had experience on the staff of the South Carolina State Hospital at Columbia. She became a member of the American Psychiatric Association in 1956.

She was the wife of Dr. Daniel M. McFarland, Chairman of the Department of Social Studies at the Atlantic Christian College in Wilson, N. C.

RIO DE JANEIRO PSYCHIATRIC ASSOCIATION.—This new organization was founded August 7, 1961 with 144 founding members. On November 20, 1961 a constitution was adopted and officers were elected: President—Dr. Pedro Pernambuco Filho; Vice-President—Prof. José Lemo Lopes; First Secretary—Dr. William Asmar; General Secretary—Dr. Paulo Marchon; First Treasury—Dr. Almir Almeida Guimarães; Second Treasury—Dr. Rawlinson Prestos Lemos.

THE BOSTON SOCIETY FOR GERONTOLOGIC PSYCHIATRY, INC.—The Boston Society will hold its third annual scientific meeting, Nov. 3, 1962. The all-day symposium will be devoted to the subject of "Emotional Disorders in the Aging Process." Speakers tentatively scheduled are Dr. Helene Deutsch, Maxwell Gitelson and Sidney Levin.

For further information, contact Dr. Norman E. Zinberg, 330 Brookline Avenue, Boston 15, Mass.

PRIMATE RESEARCH.—The U. S. Public Health Service has announced grants to Harvard and Tulane Universities totaling \$5 million for the construction and operation of primate research centers. Construction of the centers will begin early in 1963. The total grant is divided equally between the two universities.

CENTRAL OFFICE STAFF CHANGES.—President C. H. Hardin Branch announces that

the Executive Committee of Council, meeting on June 18, 1962, received and accepted the resignation of Dr. Mathew Ross as Medical Director of the American Psychiatric Association.

Effective July 15, 1962, Dr. B. W. Hogan, formerly Assistant Medical Director, was appointed Acting Medical Director. A "Search Committee" has also been selected to recommend a successor to Dr. Ross comprising Dr. Jack R. Ewalt, Chairman, with Doctors Francis J. Gerty, William G. Menninger, Mabel Ross, John R. Saunders, John C. Whitehorn and David C. Wilson.

Dr. Ross succeeded the first Medical Director, Dr. Daniel Blain, in 1958. He has accepted a Fulbright Award for Research for 1962-63. As a Fulbright Research Scholar he will spend the year studying psychiatric facilities and practices in the Netherlands. He will be affiliated with the University of Groningen.

Dr. Ross is congratulated on the honor thus accorded him and takes with him the best wishes of the Association.

UNFINISHED TASKS IN THE BEHAVIOURAL SCIENCES.—This is the title of a symposium to be held October 13-14, 1962 at the Chicago Medical School. A distinguished staff of speakers, local and from other countries will conduct the symposium, which will be opened by an address by Dr. Percival Bailey, Director of Research, Illinois State Psychiatric Institute.

HIGH ROAD TO MENTAL HEALTH.—This 16-page booklet is "a summary and brief interpretation of the principal recommendations from a 5-year study of psychiatric treatment services in Canada, by the Canadian Mental Health Association's Committee on Mental Health Services." Copies are available at 50c each (35c in quantities of 10 or more) from the Canadian Mental Health Association, 11½ Spadina Rd., Toronto 4, Canada.

NEW YORK UNIVERSITY SCHOOL OF MEDICINE TRAINING FELLOWSHIP.—New York University Medical Center is offering a 3 months Training Fellowship, with stipend

of about \$1,000 in Neuroanatomy and Neurophysiology, beginning March 4, 1963. Candidates holding the M.D. or Ph.D. degree and interested in teaching or research in these subjects are eligible. Applications should be in by January 1, 1963. For information, apply to: Dr. Louis Hausman, Department of Anatomy, New York University Medical Center, 550 First Avenue, New York 16, N. Y.

INTERNATIONAL COUNCIL OF GROUP THERAPY.—Present officers of the Council are: President, J. L. Moreno, M.D.; First Vice-President, S. H. Foulkes, M.D.; Second Vice-President, Serge Lebovici, M.D.; Treasurer, A. Friedeman, M.D.; Secretary, Berthold Stokvis, M.D. The Board of Directors includes: J. Bierer, M.D.; J. Favez-Boutonnier, M.D.; Zerka T. Moreno, M.D.; E. E. Krapf, M.D. Inquiries as to the Third International Congress of Group Therapy may be directed to: P.O. Box 311, Beacon, N. Y.

CONGRESSIONAL GRANTS FOR MENTAL HEALTH 1962-1963.—The National Committee against Mental Illness reports that grants for the coming fiscal year have been voted at \$143,599,000. This is approximately \$35,000,000 over last year's appropriation. The most important feature of the new program involves \$4,200,000 to be allocated as matching grants to the states for carrying out recommendation of the Joint Commission on Mental Illness and Health.

MENTAL HEALTH BOOK REVIEW INDEX.—Vol. 7, 1962, Whole No. 12. With an editorial: The conservation of knowledge about human behavior. xiii, 66 pp. This Review Index, sponsored by the World Federation for Mental Health and others, is now available. Annual subscription: \$3.00. Address: "The Index," c/o Miss Lois Afflerbach, Paul Klapper Library, Queens College, Flushing 67, N. Y.

MOUNT SINAI HOSPITAL INSTITUTE OF PSYCHIATRY.—This Institute in New York

City, due for completion in the autumn 1962, will receive from the NIMH five training grants for training in adult and child psychiatry, aggregating \$800,000. This institute is reported to be the largest psychiatric unit of a general hospital in the United States.

AMERICAN ORTHOPSYCHIATRIC ASSOCIATION, INC.—The Board of Directors of the American Orthopsychiatric Association have appointed Leon Eisenberg, M.D., as Editor of the *American Journal of Orthopsychiatry*, to succeed George E. Gardner, M.D., who has resigned after 14 years. Dr. Eisenberg will begin his work with the January 1963

issue of the *Journal*, filling out Dr. Gardner's term and continuing through April 1966, serving a full three-year term of his own.

Dr. Eisenberg is a member of the Subcommittee on Classification of Mental Illness of the United States National Committee on Vital and Health Statistics, and of the Advisory Editorial Board of the *Journal of Child Psychology & Psychiatry*.

The Orthopsychiatric Association has appointed Grace McGraw Smith to the newly instituted position of Managing Editor, with offices at the Association's headquarters in New York City.

All editorial communications should be sent to the *American Journal of Orthopsychiatry*, 1790 Broadway, New York City 19.

CUSTOM

It exercises over great multitudes an almost absolute empire, regulating their dress, their education, their hours, their amusements, their food, their scale of expenditure; determining the qualities to which they chiefly aspire, the work in which they may engage, and even the form of beauty which they must cultivate. It is happy for a nation when this mighty influence is employed in encouraging habits of life which are beneficial, or at least not gravely prejudicial to health. Nor is any form of individual education more really valuable than that which teaches the main conditions of a healthy life and forms those habits of temperance and self-restraint that are most likely to attain it.

—W. E. H. LECKY

BOOK REVIEWS

THE VAMPIRE IN EUROPE. By Montague Summers. (New Hyde Park, N. Y. : University Books, 1962, pp. 329, incl. index. \$7.50.)

This is a new edition of the book published in 1929 which followed another titled *The Vampire, His Kith and Kin* published the previous year. This earlier volume dealt with the history of vampirism in nearly all parts of the world save Europe, and from the remotest antiquity. The book with the present title deals with Europe, and therefore serves to fill out the picture. The original volumes were illustrated, showing vampires in action. The present edition unfortunately omits pictures.

It differs also from the earlier ones in another important feature. It contains a valuable biographical essay by Father Brocard Sewell, a Carmelite monk, about Montague Summers who was almost as mysterious as the characters whose natural history, world-wide prevalence and age-old occupancy of the planet he has so horridly-delightfully and authoritatively described. This biography, all too brief (pp. 10), was needed to complete the story.

Summers apparently delighted in creating mystery or allowing mystery to grow about him and took no trouble to clear it away. The author of the biographical essay admits that Montague Summers was a *bona fide* Catholic priest, but states that his name does not appear in the clergy lists and urges utmost caution in accepting supernatural data discussed in this book as representing the views of the Church. Summers maintained a chapel in his dwelling where mass was regularly said. Also, dressed in full canonicals, he would occupy a box at the theater and guffaw heartily at bawdy jokes.

He died suddenly in 1948 at the age of 67. He had written Volume I of his autobiography (not yet published); but Volume II, dealing with his ecclesiastic relations and his witchcraft, werewolf and vampire investigations, was still to write.

There is a mystery to be cleared up concerning his death and matters immediately sequent. His male secretary and heir followed Summers shortly in death, and all the latter's private papers and literary remains, except Volume I of the autobiography, completely disappeared. Father Sewell assures us that the manuscript of Volume I is in his possession and is being edited for publication, and that over the years he collected material on all aspects

of Summers' life, and this will also be published and may have to serve as a substitute for Volume II.

In how far did Montague Summers accept as real the various features of occultism to which he devoted so much time and described so fully? He stated in so many words that he believed in "the fundamental truth, which however exaggerated in expression or communication, essentially informs the Vampire tradition." He had lived with vampires on the basis of first hand information, gathered in the course of years in various parts of the world.

The known facts of his life suggest anything but credulity, but his case histories do not suggest that he sought to discourage credulity in his readers. Among other denizens of the nightmare world he recounts the activities of *Varney the Vampire* and of *Dracula*. (The latter appeared on the stage some years ago, with nurses stationed in the theater to minister to fainting ladies.)

If there be any who are unfamiliar with the biology of vampires, it may be stated that they are persons who have lived and died—*ante mortem* perhaps as werewolves—and who now maintain their vitality by sucking the blood of sleeping persons, preferably from the throat, and whose life may thus be drained away. And these are the creatures that this book is about. "And don't forget," as the epilogue to *Dracula* comfortingly assured, "that there are such things."

C. B. F.

CLINICAL MANAGEMENT OF BEHAVIOR DISORDERS IN CHILDREN. Second Edition. By Harry Bakwin, M.D., and Ruth Morris Bakwin, M.D. (Philadelphia : W. B. Saunders, 1960, pp. 597.)

This is the second edition of an unusually excellent, comprehensive book previously extensively reviewed. Drs. Bakwin strongly feel that the care of psychologic disturbances in childhood "is primarily the concern of the physician who cares for children." The encyclopedic range of topics, the eminently readable, well printed pages, the references and good index are a tribute to the knowledge Drs. Bakwin have of the needs of those who try to cope with emotional disturbances of children.

The authors present the various topics with authority, obviously holding to what are the facts known today and with the emphasis on

clinical management based on an understanding of the particular problems. The section on Diagnosis and Treatment of Behavior Disorders in Children is a gem. If one is interested in pursuing a special topic, why there are key references to help. Drs. Bakwin do not pretend to be exhaustive in dealing with the extensive range of problems but the basic facts and clinical pictures are admirably presented.

Pediatricians, general practitioners, psychiatrists will find this book useful and valuable. Even child psychiatrists will find it a useful volume, although they may dispute the treatment approach here and there. Certainly psychiatry residents, including those in child psychiatry training, ought to have this book as one of the texts. If one is analytically trained or oriented, one may take issue with the management of the problems as proposed by the authors. This by no means reduces the value of the work which does not pretend to be an analytic approach to behavior disorders in children. In these days of endless books, it is refreshing to see such a scholarly and significant volume.

JOSEPH D. TEICHER, M.D.,
Beverly Hills, Calif.

THE PSYCHOLOGY OF DEAFNESS. By *Edna Simon Levine, Ph.D.* (New York: Columbia University Press, 1960, pp. 381. \$7.50.)

The psychological consequences of deafness have been difficult to define. While the notion of a "deaf personality" has been effectively dispelled, it is still clear that deaf individuals do have in common many similar problems. The major focus of this book is the exploration of the deaf or hard of hearing person's world, in order to clarify these problems and to help provide a basic understanding for those who would work professionally with the deaf.

The book begins with a detailed presentation of the implications of hearing and impaired hearing. This is followed by a discussion of rehabilitation settings and problems of adjustment to disability. The third section deals with the psychological examination, and a final chapter is devoted to research needs for the area.

The uneven quality of this book is especially apparent in the section on psychological assessment, even though this topic is of major significance for the book as a whole. Some tests are discussed in detail; others seemingly as important are barely mentioned. The author's experience in this area is extensive and her observations and suggestions are sound; however, her book is less valuable than it

might have been because she simply does not provide enough information about the various assessment techniques. Many of the tests are cited by name, but how they might be useful, how valid they are, or how they need to be adapted for use with the deaf, are questions that are too often left without adequate answers. Although calling for more research, the author has not made effective use of research results already available. In fact, by her repeated use of the phrase, "... in the writer's experience ...," she supports the authority of experts rather than knowledge based on research evidence.

DALE L. JOHNSON, Ph.D.,
Houston, Texas.

TRAINING FOR RESEARCH IN PSYCHOLOGY.
Edited by *Karl S. Bernhardt.* (Toronto: University of Toronto Press, 1961, pp. x + 130. \$4.00.)

In the spring of 1960, 41 Canadian psychologists, plus one invited representative from the United States, met to discuss problems of psychological research and research training in Canada. This little volume summarizes the discussions and conclusions of this conference. The emphasis is on training at the graduate level, and the impact of that training on both the quantity and quality of research in this field. The editor has done a very good job in communicating both the work and the atmosphere of the meeting. The issues are clearly stated in a series of 58 propositions, each of which was voted upon by the group, thus providing an index of the degree of controversy attending each. Also included are brief preliminary papers written by members of the conference.

Naturally, among so many propositions a few turn out to be familiar clichés: *e.g.*, "While recognizing the great importance of new knowledge it should be understood that the education of the individual research psychologist is the prime concern of all those responsible for his training." On the other hand, the proportion of well-conceived and well-stated principles is encouragingly high. The total picture that emerges suggests a real concern with the problems of providing the student not only with the tools and settings, but also with the attitudes and enthusiasms that lead to research of high quality. Certainly this book suggests that academic psychologists are not satisfied with the *status quo* in training for research; very few of the propositions are self-congratulatory.

This book is also interesting because of what

it suggests of psychological research in general, both in Canada and the United States. The problems of training research psychologists mirror the problems of research psychology. For example, considerable discussion was devoted to the place of methodology, and the problem of good research in the "soft" areas. This discussion is summarized by the statement, "Psychological research should not be limited by any one narrow view of the 'right' way to do it." Psychology as a science is struggling to find its indigenous research methodology, and areas of great importance are ignored or distorted to meet canons of scientific rigor. A hopeful note of relaxation in this rigid attitude sounds in these proceedings. Another nexus of problems concerns the applied person within a research discipline. A "liberalized conception" of psychological research was suggested in the conference as applying to the graduate student oriented toward a professional career in applied psychology. However, there is a potentially dangerous schism in psychology between some of its applied and research people. Surely the role of research in applied training cannot be defined until there is some resolution of this problem in the field as a whole. These and other problems of training reflect currents in the entire stream of modern psychology.

This reviewer has a few reservations about these discussions. Most of the matters discussed and the propositions formulated deal with general conceptions, the philosophy of research and research training. Seldom is there a concrete suggestion or a specific exploration of the sources of disagreement. Perhaps this limitation to generalities is dictated by the nature of any such conference, or perhaps the situation at any given institution is so unique that no specific proposal could find acceptance. Nevertheless, one wishes for more controversy about specifics than agreement about generalities. One also looks in vain for fresh ideas about such important problems as student selection for research training. It seems ironical that psychologists should have so little new to say about the raw materials for making a dedicated and productive research person.

In summary, this book is informative and provocative, viewed either as the summarization of the thoughts of distinguished psychologists on the subject of research training, or as a reflection of the state of psychology as a research discipline in both Canada and the United States. It merits the attention both of psychologists and persons in related disciplines who want to know more about psychological

research and researchers.

WILLIAM L. HAYS, M.D.,
University of Michigan.

THE GUTENBERG GALAXY. By Marshall McLuhan. (Toronto: University of Toronto Press, 1962, pp. 294.)

This interesting book is subtitled "The Making of Typographic Man." It is written in a rather episodic style, and is really quite fascinating, for its thesis is that literacy and the printed word have revolutioned the field of recognition of civilized man. It has taken him out of his nonliterate tribal societies and ushered him into a visual open world of specialized and divided consciousness. "The individual versus the state, thought versus feeling, art versus commerce, and science versus humanism are the most familiar of the schizoid states which we recognize as the inevitable legacy of literacy in any culture or in any period or history." But this is only one of the themes of Professor McLuhan's prismatic volume.

Typography helped to turn the vernacular tongues of Europe into mass media, and thus served to homogenize and reconfigure into collective forms the dissociated masses of Europe, into peoples with a national consciousness, and the author suggests, a collective unconscious. As Claude Bernard remarked, it is altogether unimportant whether a theory be right or wrong. The important thing is that it should be fruitful. That Professor McLuhan's book will fructify the minds of all who read it, I have not the least doubt. It is an original and highly stimulating work.

ASHLEY MONTAGU, Ph.D.,
Princeton, N. J.

EXPERIMENTAL PSYCHOLOGY. By Burton G. Andreas. (New York: John Wiley & Sons, 1960, pp. xii+595.)

This book is a most commendable elementary presentation of aspects of method and content of psychology in a brief and stimulating fashion. The apparent intention is not only to convince the student of the value of a scientific study of human behavior, but also to give him a "feeling of participation in an on-going scientific enterprise."

Part I deals with "general principles, methods and techniques of the field," and Part II "shows how general methodology and specific techniques have been applied to major problem areas in research." The organization of the material is such that both parts may be studied simultaneously. In the first part, psychology is

viewed as that branch of science which "seeks to express the laws of behavior," and the research process is described with concepts such as operational definitions, dependent and independent variables, laws, hypotheses and the design of experiments in relation to making statements of the form, "if A, then B." Measurement and scales are considered in terms of the degree to which they possess properties of the number series. Descriptive and sampling statistics are presented, "merely as an adjunct to a laboratory course." Excellent summaries are presented on psychophysical and psychological scaling techniques. Part I concludes with some suggestions for writing a research report, and a terse statement on the relation of theory to research.

Part II includes good summaries of some of the variables relevant to vision, hearing, verbal learning, perceptual-motor skills, retention, transfer of training, problem solving, and social processes. The author's intent is that the student will see in these several content areas specific applications of the more general principles presented in Part I.

The language is not too technical, bordering, if anything, on the popular, rather than the rigorous. Illustrations are selected so as to be understood easily and to clarify readily points in the presentation.

A book on this topic must be considered in terms of the magnitude of the problem of writing a comprehensive text. Complete coverage of all relevant aspects of method and content of psychology in a single elementary book is impossible. Selection is essential. As is pointed out, not only are historical reviews, physiological mechanisms and particular theoretical positions omitted, but also are illustrative studies limited to those on human subjects. Limited space has been devoted to the mathematical concept of probability, and to the manner in which it is utilized to permit scientific statements in the absence of complete knowledge. The logical status of theory in the whole research process is covered in a rather cursory fashion. Human conditioning, a significant content area, is not included. The addition of chapters dealing with perceptual-motor skills, and with social processes in place of the traditional chapters on chemical and cutaneous senses seems a desirable change.

In spite of these deliberate omissions, abbreviations and changes, the book admirably succeeds in accomplishing its goal—namely, considering method and content in an interdependent relation to each other. In comparison with earlier books on this subject, this text is significant in that method and content are both

stressed, suggesting the close dependency of content on method. As a science progresses, changes in material included in books of this sort are expected. Social processes and other areas not previously studied by rigorous research methods can now be included as experimental psychology, indicating that the title of the book does not designate the same limited area that it once did.

PATHOLOGISCHE REAKTIONEN DER PERSONLICHKEIT (Pathological Reactions of Personality). Vol. 1. By *Nicola Schipkowensky*. (Vienna : Wilhelm Maudrich Verlag, 1960, pp. 210.)

Dr. Schipkowensky, who is professor of psychiatry at the University of Sofia, Bulgaria, is well-known for his many scientific publications in all fields of psychiatry (e.g., *Schizophrenie und Mord*). His teaching represents a combination of Kraepelinaean and Pavlovian psychiatry which is very well reasoned and plausible. Many North American psychiatrists have a tendency to ignore these points of view, partly because of difficulty in gaining access to up-to-date material on these subjects and partly because of increasing divergencies of view points. The present book gives an opportunity for those who read German to get acquainted with a fine sample of this particular band of European psychiatry.

This is the first volume of a work devoted to the pathological reactions, but it contains much more than that. First of all, it is a reassessment of the much discussed problem of psychiatric nosology. The author is well aware of the attacks which recently have been launched against a supposedly "outmoded" psychiatric nosology, but maintains that a firm nosologic system, based on the concept of specific disease entities, is both necessary and proved by the facts. It is necessary because it is the only system which brings clarity to psychiatry from the theoretical as well as the practical point of view, but above all it is proved by the facts, insofar as these are submitted to an impartial analysis. The main error of the anti-nosologists has been their confusion of syndrome and disease entity. Because in various psychiatric and neurological conditions one can see depressive states, epileptic fits and symptoms resembling schizophrenia, they denied the existence of manic-depressive illness, genuine epilepsy and schizophrenia proper, as if both were not compatible.

The first part of the present volume is de-

voted to a much needed clarification of concepts, among others the concept of psychiatric reaction. Schipkowensky uses this word strictly in its original meaning, not in the meaning which Adolf Meyer has given to it in North America. The general substitution of the terms "schizophrenic reaction" and "psychotic depressive reaction" for "schizophrenia" and "melancholia" amounts to making the word "reaction" synonymous with "mental condition" and robs it of any real meaning. Schipkowensky uses the word "reaction" only in those cases, 1. Where a definite relationship of cause and reaction can be posited, 2. Where this relationship is psychological with an implied "psychogenesis," "psychodynamics" and "possible removal through psychotherapy," 3. Where the patient actually experiences the cause subjectively. Such reactions need not be immediate; they can appear many years after the cause through the effect of a precipitating agent. The reaction can also expand from the trauma itself to the whole surrounding circumstances, and become very complex and elaborate (as is the case in hysteria).

Among reactions of the personality, some take the form of neuroses, others present a psychotic picture. The author accepts the existence of reactive depression, reactive epileptic convulsion and reactive schizophrenic picture, but insists that these should not be confused with manic-depressive illness, epilepsy and schizophrenia. These psychogenic psychoses will be dealt with by Schipkowensky in the second volume. The present volume contains descriptions and analyses of neurasthenia and anxiety neuroses from the author's point of view.

Schipkowensky's book is extremely informative and concentrated and contains a wealth of facts and clinical data. It distinguishes itself by clarity of thought and sharpness of definition. The author shows considerable scholarship and a profound knowledge of all psychiatric currents in Central Europe, France and America, as well as of Pavlovian psychiatry, from which the book contains ample material.

H. ELLENBERGER, M.D.,
Montreal, Canada.

synthesis of the vast amount of recent experimental and theoretical literature. The volumes can be read independently. They are well written and well thought out. Every major statement is supported by evidence from numerous experimental findings from the most diverse camps. He has integrated various sources of information in a highly systematic way. The volumes provide an excellent review of the literature. Even to the galley proofs, the author added new experimental evidence. One gets the picture of an exciting adventure in ideas which never ends.

The model on which Mowrer's thinking is based is a mechanical one, having its analogue in modern developments in cybernetics. While he rejects teleology, he believes that behaviour is purposeful in the way that the behaviour of complex, automatic, self-regulating machines is purposeful. The continuous adjustments that occur within the human organism on all levels are for the purpose of maintaining homeostasis.

His theoretical junction is between that of Hull and of Tolman (whom he greatly admires).

Learning Theory and Behaviour consists of a historical and developmental exposition of behaviourism. The two main schools, that is, those of Pavlov and Thorndike, are reviewed. In lucid, step-by-step fashion Mowrer builds up the case for his revised two-factor theory of learning, drawing extensively on numerous experimental studies to support his position. Mowrer no longer sees learning as two-factored on the basis of autonomic fear conditioning and instrumental habit formation. All learning is now a matter of conditioning, i.e., sign learning. His theory remains two-factored only because he postulates basically two different kinds of reinforcement processes. His argument culminates brilliantly in chapter 7 with a novel interpretation of the phenomenon of habit as facilitation of behaviour depending on the conditioning of the "feedback of hope." Habits are, therefore, not dependent upon increased conductivity between S_d-R_1 but upon increased conductivity between stimuli which are produced by R_1 and the phenomenon of secondary reward or hope.

Mowrer states that meanings, emotions and interpretations which become attached to particular situations or stimuli are basically reflexive (involuntary, autonomically mediated). Nevertheless, he insists that the organism is capable of choosing, selecting and directing his behaviour. Choice is possible because what is learned (conditioned) is not a specific S-R bond (brain-to-muscle pathway) but an emotion (hope, fear, relief, disappointment). An

LEARNING THEORY AND BEHAVIOR. pp. 555, \$6.95. LEARNING THEORY AND THE SYMBOLIC PROCESSES. pp. 473, \$8.50. By *Hobart O. Mowrer*. (New York: John Wiley and Sons, 1960.)

These two volumes are a comprehensive attempt to present a systematic behaviour theory which the author hopes will effect a broad

emotion is operationally defined as a conditioned response to primary drive increment or decrement (fear or hope). Its function is to motivate and to select on the basis of the informational feedback from the senses, whereas primary drive increments and decrements reinforce, *i.e.*, mediate learning. "Therefore learning . . . must be more a matter of control, of coming to *want* or *not want* to make a particular response, than of capacity. It is only the relative *attractiveness* of the response, it seems, that is altered by learning; and *this* alteration is unequivocally assumed to be neurologically based" (p. 221). (However, Mowrer does not make it clear whether this is a central or a peripheral phenomenon.) It follows from this that "a given behaviour sequence once set in motion is not ineluctably determined, but is, rather, subject to continuous modification on the basis of the 'meaning of the situation' and it is sensed or perceived from moment-to-moment. In other words, behaviour is a continuous, ongoing function of the informational feedback from *all senses*, internal and external" . . . (p. 309.)

The exposition of *Learning Theory and the Symbolic Processes* is provocative and fascinating because essentially it breaks new ground in offering the concept of mediation to bridge the gap between animal learning where signs are the mediators and human learning where symbolic processes are the mediators. Mowrer's first task is to show that images are the cognitive and representational part of the meanings which words come to possess. The child learns to repeat words for the autistic gratification it gives him—since the words are connected with positive reinforcement. However, language is only effective instrumentally in the presence of another organism who is now expected to carry out the needs of the individual speaking the words. The sentence is therefore a conditioning device. Its chief function is to produce new associations, new learning just as any other paired presentation of stimuli may do. It is obvious from this that reality which is not present can be represented by images, concepts and symbols. The reality of images, once established, accounts for the phenomenon of memory and imagination. Since what is learned by the organism is primarily emotional and not S-R bonds, a particular behaviour is willed or chosen "because its image, or anticipated occurrence, arouses hope; whereas its nonoccurrence or incorrect occurrence arouses no hope, or even fear. There is presumably, as James implies, a kind of *scanning* of various possibilities which occurs in

connection with response selection; and here symbolic behaviour plays the crucial role" (p. 286). The most exciting chapter of the second book is chapter 7, entitled "Learning Theory, Cybernetics and Consciousness." It is here that Mowrer makes clear how choice operates and in what sense behaviour is flexible and free. The rest of the book deals with problems that attempt to show the probabilistic nature of learning and of reinforcement. Mowrer's position is that "if life were *not* chancy, *learning* would be unnecessary" (p. 331), but since it is, the genuine causal relationship (which is the goal of science) is a matter of probability. It can be established through the principle of learning by contiguity on the basis of repetitive occurrences ". . . living organisms must be capable of learning 'the causal texture' of an environment, not only when cause-and-effect relationships are uniform and consistent, but also when they are irregular and inconsistent; *i.e.*, under conditions wherein reinforcement is not certain but merely more or less *probable*" (p. 333).

The last chapter on social learning explores the problems of social conditioning in animals and in humans. The pathology of thought is considered in terms of image and emotion; ". . . for an individual to 'know what it is all about,' a conditioned stimulus must arouse not only the appropriate affect but also a proper image or memory of the unconditioned stimulus. If the affect occurs but the image does not, we have the prototype of what 'disproportionality of affect' which is said to be the hallmark of psychopathology" (p. 412).

Mowrer also attempts to explore the question of conscience (internalization of right and wrong) and moral responsibility. While this last chapter may be described as the most doubtful part of the book from a theoretical and experimental point of view, it is, nevertheless, a courageous and highly admirable attempt. "Any account of human motivation and personality that ignores the 'moral strivings' of man is grossly incomplete and, by that very fact, misleading and dangerous" (p. 395). One can disagree with Mowrer's interpretation of "moral strivings" but the introduction of the concept of moral responsibility appears to be timely.

Mowrer's position may be summarized in his own words. "The whole thrust of revised two-factor learning theory has been to reintroduce the problem of choice (where it had been quite abolished by the reflexology of Pavlov and the stimulus response 'bonds' of Thorndike); to show that hopes and fears

(which are the dynamic conditioners of choice) themselves imply not only 'probabilities' but also the nature and magnitude of risks (promises and threats); and to provide, generally, a conceptual and explanatory framework of scope and power" (p. 319).

One certainly gets the feeling that the need to put "free will" or choice back into the interpretation of human behaviour, as opposed to determinism, has been the main motivating force of Mowrer's theoretical position; and he has succeeded convincingly in putting this across. The two volumes are certainly an admirable and significant contribution by an original thinker and a thorough-going scholar. In a hey-day of theories erected upon, and dealing with, fragmented bits of behaviour, it is gratifying to this reviewer to find here the old-time systematizing.

GESELLSCHAFT, KULTUR UND PSYCHISCHE STÖRUNG. (Society, Culture and Psychic Disturbance.) By *Jakob Wyrsh*. (Stuttgart: Georg Thieme Verlag, 1960, pp. 120.)

This well written monograph is, apparently, designated for the lay reader. That explains its attractive popular style. The author struggles frequently with psychiatric definitions. For our "mental diseases," the German uses "geisteskrankheiten," i.e., diseases of the "geist," "geist" meaning: ghost, daemon, spirit, mind, intellect, etc. The analysis by the author of this term and its ramifications creates a great deal of confusion. Quotations from Hippocrates, Aristotle, Thomas Aquinas, Nietzsche, Lombroso, Bleuler, Mann and others do not make it clearer.

Human progress has its negative aspects too. We reduced infectious diseases, but arteriosclerotic conditions, unknown to primitive civilizations, are on the increase. With longevity the psychoses due to aging have become more frequent, though their interrelationship is still uncertain. Contrary to our anticipation, both World Wars did not increase the incidence of mental diseases. Exogenous psychoses as a result of alcoholism have diminished, primarily, because of alcohol control, while neurological and psychotic involvements due to lues have almost disappeared, thanks to medical progress.

The author quotes verbatim the ramblings of confused patients, with their incoherent and neologistic material, illustrating their distorted inner world. He notes particularly their regression to an infantile vocabulary.

Dr. Wyrsh discusses various therapies in-

cluding art, and believes that the art of the surrealists and schizophrenics can hardly be distinguished, one from the other.

ELECTRICAL STIMULATION OF THE BRAIN.

Edited by *Daniel E. Sheer*. (Austin, Texas: University of Texas Press, 1961. \$17.50.)

This volume will prove a useful tool to the active investigator, and an informative text for those who desire a knowledgeable outline of this field of endeavor.

Those chapters devoted to the description and results of experiments are readable and cover thoroughly the subject. A more elaborate presentation of this material would seem superfluous.

The earlier chapters devoted to techniques in construction of electrodes, and more particularly those concerning the character of function of the instrumentation are most useful. One might suggest that even more consideration could have been given to this area; for example, the physical properties of the metals used in electrodes and electronic circuitry involved in stimulators are important facets of any experiment concerned with stimulation of the brain.

In summary, the editor and authors are to be commended for producing a most valuable addition to the library of the experimental neurologist.

Detroit, Mich.

PLAINVILLE FIFTEEN YEARS LATER. By *Art Gallaher, Jr.* (New York: Columbia University Press, 1961, pp. xvi + 301. \$5.00.)

In 1945 James West (Carl Withers) published a book entitled *Plainville, U. S. A.* That book presented a study of a relatively isolated American agricultural community, as seen through the eyes of an anthropologist. The present work is an independent re-study of the same community fifteen years later. It is a most revealing study, and shows, I believe, the general trend in the United States, where agricultural communities are increasingly coming under the influence of the cities, with all the social and psychological changes that this involves. As a study in social change this volume constitutes a valuable contribution which will have great practical value in facilitating the untraumatic transition from rural to suburban and urban existence.

ASHLEY MONTAGU, PH.D.,
Princeton, N. J.

IN MEMORIAM

CARNEY LANDIS

(1897-1962)

Carney Landis, Chief Research Psychologist at the New York State Psychiatric Institute and Hospital, died on March 5, 1962 after a long and trying illness during which he kept up his lifetime pattern of work. Not a man of strong physique and often plagued by illness, he set a pace in his laboratory that few could equal. He first came to the Psychiatric Institute as Research Associate in 1930 in the rapidly developing pattern of appointing associates from those scientific disciplines allied to medicine. A man of insatiable curiosity and tremendous drive, his research touched every area of psychopathology. In his more than 30 years at the Institute he established an international name for himself in the field of psychopathology and added immeasurably to the growing lustre of the Institute's research reputation.

Landis was born on January 11, 1897 in West Alexandria, Ohio. After a brief stay at Carnegie Institute of Technology he shifted to Ohio State University where he majored in psychology and received his A.B. in 1921. He was granted the M.A. from Dartmouth College in 1922 while teaching as an instructor in psychology. Immediately thereafter he transferred to the University of Minnesota where he obtained his Ph.D. in 1924. Following this he spent two years as a National Research Council fellow, the first at Minnesota, followed by a year at the University of London. In 1926 he was appointed Assistant Professor of psychology at Wesleyan University in Middletown, Conn., and was promoted to Associate Professor in 1928. The invitation to the Psychiatric Institute came in 1930 and Landis left Wesleyan to remain in New York the rest of his life. He had a coordinate appointment as Professor in the department of psychology at Columbia University and this satisfied whatever academic leanings he had. There were brief teaching visits to Harvard, the University of California at Los Angeles, and the

University of Washington. These were pleasant interludes, but Landis preferred the freedom and the research resources of his laboratory at the Institute. In 1948 he made a visit to Colombia on a teaching and service mission and was awarded the honorary degree of Doctor of Science from the University of Antioquia in Bogata.

As an undergraduate at Ohio State he had been influenced by the prevalent behaviorism of Weiss; and J. B. Watson and K. S. Lashley added their influence at a later date. Yet it would be a mistake to call Landis a behaviorist in any narrow sense. His empiricism went deeper than that. To him, as to so many of his psychological contemporaries, formal behaviorism was but one surface manifestation of the deeper conflict between the purely rational and the experimental approach. He saw no need to deny consciousness as a phenomenon, and introspection as an experimental method had a place in his investigations, but the ultimate criterion for truth always remained the experimental confirmation of hypotheses under controlled, objective conditions. His laboratory empiricism was complemented by an insistence on careful and complete bibliographical investigation, and by a lifelong fascination with elaborate instrumentation. Complicated apparatus not only epitomized for him the ultimate in objectivity of observation and recording, but it satisfied the universal male desire for intricate gadgets. Whatever the problem under investigation his laboratory was always equipped with the latest and most efficient mechanical devices available.

His rigid laboratory empiricism demanded that he be eclectic in his theoretical affiliations. For him truth could never submit to any narrow, systematic restrictions. It also meant making professional enemies as well as friends, for he soon discovered one of the uncomfortable truths of an honest eclecticism—the teaching eclectic can be comfortable and happy for he can

preach the best of his friends' contributions, but the eclectic experimenter is doomed to some discomfort and unhappiness for he must investigate and uncover many of his friends' errors.

Some of this was reflected in Landis' relations to psychiatry. The weight of Landis' contribution to experimental psychopathology tended to minimize his experience in the service aspects of clinical psychology, yet he had done psychotherapy as well as studied it. He was no enemy of psychotherapy; but he was often classed as such, because of his insistence on the fact that there is as yet little if any experimental evidence of its efficacy, and because of his firm belief that faith, in and of itself, cannot be the basis for a science of medicine. To the timid therapist who would protest that the delicate processes of psychotherapy should not be exposed to the blunt instruments of contemporary scientific investigation, he would answer that overfeeding at the sympathetic fountains of unlimited faith might be equally damaging to their development.

His attitude toward psychoanalysis reflected the same conflict, a conflict typical of his generation of psychologists. There was a beginning excitement about and enthusiasm for the dynamic insights of psychoanalysis, a realization of their necessary complementation of the previously largely organic orientation in psychiatry, followed by an increasing disillusionment with some of the verbal (theoretical?) excesses committed in its name. To this disillusionment Freud's open antiexperimentalism was a major contributing factor. Landis could be sympathetic to psychoanalysis, as he was in pointing out in 1935 the relative neglect in textbooks of abnormal psychology of psychoanalytic doctrine; and he could be cruel, as he was in 1940 in saying of the average psychiatrist that "he has no adequate knowledge of scientific reporting, no comparable technical vocabulary, and but the vaguest ideas of scientific logic."

His own analysis was undertaken in large part because of a genuine, scientific interest. Granted that no analysis is begun or continued on a purely didactic basis, he entered on analysis in a spirit of honest inquiry. Analysis is one situation in which distance

does not lend enchantment, and there seems to be an inverse relation between the analyst's enthusiasm and the subsequent passage of time. But a remark of Landis' at the time points up a universal dimension of psychotherapy. When teased by the comment that his analysis had revealed nothing about himself that his friends had not already pointed out, his reply was, "That may be true, but it is different when you tell it to yourself."

Carney Landis was not by nature a theoretician. He was too busy reporting observable phenomena to find time for filling in the systematic gaps in the relationships between his data. His one major venture into systematics was a disappointment to him. In 1947 in the *Journal of Comparative and Physiological Psychology* he published a paper on "A Modern Dynamic Psychology," originally presented in a symposium sponsored by the American Association for the Advancement of Science. It is a timeless, beautifully stated exposition of the eclectic position in which he deals with behavior as resulting from the interaction of heredity, constitution, and environment. It is closely reasoned, eminently fair, and not without humor when he describes delirium tremens as "a condition which may be said to depend largely on maturation and exercise with but little evidence of an hereditary component"; yet it never received the attention Landis felt it merited, no doubt because the sweet reasonableness of the eclectic position attracts neither the press, the historian, nor the fanatic adherent in search of a cause.

Despite the paucity of his systematic and theoretical writing, his productivity in research had an important impact upon the mental health sciences. His early concentration upon the electrophysiological phenomena of the body helped to bring methodological sophistication and maturity to a field which sorely needed it. Following his publication with Page in 1938 of *Modern Society and Mental Disease* there was no further excuse for the naive manipulation and misinterpretation of the statistics of mental disorder which had been common practice until then. This was but one example of his life-long interest in and support of the emerging sciences of biometrics and

epidemiology. His work on the development of biographical inventories as a diagnostic technique was pioneering in a method now firmly established as a standard selection procedure since World War II. His work with Mettler on the Greystone project in psychosurgery and his later work on flicker fusion and in pharmacology all helped to further the understanding of the physiological substrate of behavior which he as an eclectic felt to be an important complement of the dynamic, environmental factors so popular at the time.

It would be impossible here to list all his interests and accomplishments. His textbook with Bolles in 1950, *Abnormal Psy-*

chology, was a landmark in the field of experimental psychopathology. At his death he was preparing a new book for publication, *The Varieties of Abnormal Experience*. In evaluating his influence one cannot overlook the sympathetic encouragement he gave so many of his younger colleagues and his ready assistance to all those dedicated to the research investigation of mental disorder no matter what their special area of interest might be. Our memories of Carney Landis as a man may dim with time, but the cumulative weight of his scholarship will be felt in the field of experimental psychopathology for generations to come.

William A. Hunt

REACTION TO EXTREME STRESS : IMPENDING DEATH
BY EXECUTION¹HARVEY BLUESTONE, M.D., AND CARL L. MCGAHEE, M.D.²

We conventionally think of death as "the worst thing" that can happen to us. Knowing, as we all do, that we will die in some vague future does not impose any great stress. The man in the grip of a relentlessly fatal disease has to cope with much more severe stress. But mercifully, his death date is not fixed and he can always hope to see tomorrow's sun rise. Presumably, the greatest of stresses would be imposed on the man who knows he is going to be put to death—and knows just when that will be.

We have studied 18 men and one woman in the Sing Sing death house. Because of the inmate utilizing opportunities for appeals for clemency or commutation there is adequate time for repeated psychiatric interviews and psychologic examinations.

These men are housed in an area detached from the rest of the prison. They have few visitors, though the authorities impose no restrictions on visiting. One might expect them to show severe depression and devastating anxiety, yet neither symptom was conspicuous among these 19 doomed persons. By what mechanisms did they avoid these expected reactions to such overwhelming stress? Do their emotional patterns change during a year or two in a death cell? And, do these defenses function to the moment of execution—or do they crumble towards the end?

The 19 histories had certain features in common. All had come from deprived backgrounds. All but one came from homes where the father was missing (deserted, dead, unknown, or separated) during the childhood or adolescence. Practically all had been brought up (during their growing years) in institutions or foster homes. Not one had an education better than that of tenth grade. Some were illiterate. Their intelligence varied from an IQ of 60 to one

with an IQ of 140. All had been convicted of murder. None of the murders was long planned: they were impulsive. Many were committed in connection with a felony. The world appeared as a hostile, dangerous, and menacing place, and they had reacted in their way—by aggression, suspiciousness and cynicism.

The following are brief summaries of the reaction of some of these men to their imprisonment in the death house. (For collective data v. Table 1.)

1. This man has the longest residence in the death house of those in this study, approximately 2 years. An overt confirmed homosexual, he maintained a calm conviction that he would be ultimately pardoned. This belief remained bolstered throughout by an unchanging contention that he had been framed by the legal and medical authorities involved in his prosecution. Psychological testing showed a man of average intelligence with considerable withdrawal from real emotional interaction with others. Defense mechanisms of denial and projection were effective in warding off anxiety and depression despite prolonged incarceration in the death house.

2. This inmate is the only woman in this series. She is of dull intelligence, acts in a playful and flirtatious manner. She was usually euphoric, but became transiently depressed when she thought her case was going badly. She frequently complained of insomnia and restlessness. These symptoms quickly disappeared when she was visited by a psychiatrist whom she enjoyed seeing and talking to in a self-justifying and self-pitying manner. Psychological tests showed pervasive feelings of insecurity, repressive defenses, and an inability to handle angry and aggressive feelings in an effectual manner.

3. This inmate is a withdrawn, sullen, uncommunicative individual. When visited in the death house he would elaborately and slowly wash his clothes ignoring examiners. He spends much of his time reading profound philosophical works which are beyond his comprehension. His intelligence is dull-normal. He has become

¹ Read at the 118th annual meeting of The American Psychiatric Association, Toronto, Canada, May 7-11, 1962.

² New York.

TABLE 1

1. Age range of death house prisoners	
18 or younger	1
19 or 20	2
21 through 25	5
26 through 30	3
30 to 35	5
over 35	3
2. Family background	
Parents together during most of childhood	1
Father unknown or deserted	7
Father divorced or separated	10
Father and mother unknown	1
3. Highest school grade reached	
Fourth or lower	4
Fifth or sixth	8
Seventh or eighth	2
Ninth or tenth	5
4. Intelligence Quotient	
60 through 69	2
70 through 79	5
80 through 89	7
90 through 119	4
120 through 140	1
5. Family status of prisoner as adult	
Never married, but had common-law spouse	5
Never married, no regular consortium	11
Married but separated	2
Living with wife	1
6. Psychological defense mechanisms used	
(Totals more than 19; some used more than one)	
Denial by isolation of affect	7
Denial by minimizing the predicament	4
Denial by delusion formation	1
Denial by living only in the present	4
Projection	7
Obsessive rumination in connection with appeals	3
Obsessive preoccupation with religion	2
Obsessive preoccupation with intellectual or philosophical matters	5

progressively more suspicious and grandiose during his death house stay.

4. This man gives a long history of delinquent behavior. He is a litigiously minded individual who states that he can appeal his case for years. He is obsessed with his own power and is convinced that a law suit against the district attorney for lost automobile tools kept that official from being reelected. He has become progressively more angry and abusive ultimately necessitating his physical isolation from other inmates. His IQ is 134. Projective tests show a chronically cold, withdrawn, narcissistically invested personality. Withdrawal, projection and denial are prominent defense mechanisms.

5. This man is at all times euphoric. He has shown little anxiety during the full year he has spent in the death house. He has led a hedonistic life and has never been able to make future plans. His inability to see beyond the day seems quite effective in enabling him to avoid anxiety and depression.

6. This inmate showed during his early months of incarceration a contemptuous indifference toward the authorities and his own plight. Gradually, however, depression appeared and became progressively more intense. This was rather dramatically reversed when the inmate presented an apparent religious conversion, which seemed to both occupy his mind and also elevate him above the authorities and his situation. However, this defense was only partially successful for this individual who had a life-long history of discharging all tensions by immediate impulsive acting-out. Psychological testing showed dull-normal intelligence and a primitive, self-absorbed, hostility-ridden personality.

8. This inmate related to examiners in an open and direct manner. He is mentally dull and preoccupied with thoughts of voodoo spells. His primary defense mechanism is denial of the possibility of being executed. This works poorly and he is chronically anxious and periodically depressed. His anger at his accomplice, who he is convinced is the cause of his difficulties, seems to relieve him of some of his unpleasant feelings. He amuses himself in working on a taunting poem which he proposes to recite when his accomplice is executed. This mechanism, too, is ineffectual and he reverts from these thoughts of revenge to a contemplation of his own plight.

9. This man is a moody individual who feels he is the victim of a Jewish plot since the judge, district attorney, and his own court appointed lawyer are Jewish. He denied his guilt repeatedly during his early days in the death house, but became progressively more confused and a few days before his scheduled execution asked the examiner for truth serum so that he would know whether or not he committed the crime. He showed alternating use of introjection and projection. He would become depressed when news of his appeal was bad, and when a stay of execution was granted he became paranoid and grandiose. He managed in some obscure way to identify his impending death with that of Lumumba, who had recently been killed in the Congo, and felt that his own execution would make him a martyr in the cause of anti-imperialism.

10. This man stands out in the series as being the one who most successfully employed

intellectualization as a means of defending against anxiety and depression. He elaborated a philosophy of life and values in which his own criminal career became not only justifiable, but even respectable. He rationalized his crimes by emphasizing the hypocrisy and perfidy of society on the one hand and by comparing himself with policemen and soldiers and others who live honorably "by the gun" on the other. This system was so effective for him that even when execution appeared imminent he maintained his hero's martyr role and disdained to request executive clemency.

11. This inmate is an illiterate, inadequate individual who was convicted as an accomplice to a robbery-murder. He had an overall IQ of 51. He showed primarily depression, withdrawal, and obsessive rumination over the details of his crime and conviction. He eventually evolved a poorly elaborated paranoid system whereby he supposedly was betrayed and framed by his girl friend and one of the co-defendants. Despite the looseness of his persecutory thinking, it was accompanied by a clear-cut elevation in his mood and reduction of anxiety.

12. This inmate, also an accomplice to a robbery-murder, showed one of the most florid pictures of any in this series. Both grandiose and persecutory themes were prominent, but the latter predominated. He maintained that his arrest and conviction were malicious frauds, and he meticulously and obsessively combed through the court record to substantiate his contentions. His arguments were labored and illogical, hinging on such points as the use of words like "who" and "whom." The paranoid mechanisms seemed to mitigate, but not completely defend him against depression.

13. He is one of the two inmates in this series who uses religious preoccupation as his major defense mechanism. He repeatedly in an almost word for word way stated his situation as follows. "No one can understand how I feel unless it happened to you. Christ came to me and I know He died for my sins. It doesn't matter if I am electrocuted or not. I am going to another world after this and I am prepared for it." As his stay progresses he becomes increasingly more hostile and antagonistic, and his behavior progressively out of keeping with his professed religious ideas. In addition to obsessive rumination, projection and withdrawal are employed to ward off feelings of anxiety and depression.

DISCUSSION

Faced with certain and ignominious death, a person would presumably be over-

whelmed with anxiety or plunge into the depths of depression. Yet this does not happen. What defense does the human mind set up against intense anxiety or a paralyzing depression? We suggest, on the basis of our 19 case studies, that the defenses are of mainly three types—denial, projection and obsessive rumination. The commonest form of *denial* is isolation of affect. "So, they'll kill me; and that's that"—this said with a shrug of the shoulders suggests that the affect appropriate to the thought has somehow been isolated. A second common form of denial is to minimize the gravity of the present situation and to take for granted that an appeal will be successful. The third and most extreme manifestation of denial, used by only one individual, was to delusionally believe that a pardon had been granted. Denial is also commonly used by persons dying of disease.

There is another phenomenon which deserves further explanation, since it may easily be confused with denial. Several cases impressed the examiners as being so immersed in the present moment as to virtually be insulated from any significant emotional relatedness with their own past or future. Thus, they do not have to deny anxiety since they do not experience it. This, incidentally, is the traditional profile of the "psychopath" who reacts only to present stimuli.

Projection is an obvious, and not uncommon, mechanism. Typically, it takes the form of persecutory delusions. At least three of our prisoners considered themselves persecuted by specific groups in the community. This mechanism converts dissolute criminals into martyrs. It is a comforting delusion. While it does not deny that death is just around the corner, it tries to lend it dignity and meaning. In some men there seems to be an almost quantitative reciprocal relationship between the use of projection and introjection so that they are either overly paranoid or depressed.

A third way of coping with painful affects is to *think furiously* about something else. Thus, the depressing thought is elbowed out of consciousness by the crowd of other ideas. We see this in a morbid obsessional concern about the preparing of appeals or pleas for clemency. One prisoner spoke to

us for an hour about whether a pronoun in the appeal transcript should be "who" or "whom." To be sure, a meticulous concern with the appeal brief is rational; in these cases, however, the concern is obsessional, ruminative and ineffective. Another type of obsession (two of the men showed this) is preoccupation with religion to the exclusion of everything else. The prisoners who developed this syndrome had involved their confederates in death sentences too, though neither accomplice had killed anyone. Presumably, this religious conversion served to blunt guilt feelings about involving the accomplices. This activity served two other purposes: it distracted them from anxiety, and it offered a route to a happy life in the hereafter. The third type of obsessive rumination is the intellectual: a dipping into philosophical thought by a man whose life had hitherto been devoted to hedonistic pursuits.

Some try desperately to mould a respectable image of themselves. This is certainly one sluiceway for draining out anxiety—as illustrated, for example, in the way in which one of the prisoners identified himself with

Lumumba and the recent world shaking events in the Congo.

The group support these men receive from fellow inmates is variable. Some are quite appealing and receive considerable emotional and even material support in terms of cigarettes and help with their correspondence. Others manage quickly to antagonize their fellows and are in turn ridiculed and tormented by them in a direct and sadistic manner. This is often true when a man gets the reputation of being a malingerer. The inmates are quite antagonistic to anyone they feel is falsifying religious beliefs or feigning mental symptoms.

CONCLUSION

Traditional ego defense mechanisms alleviate distress. They also mitigate anxiety and depression which would otherwise overwhelm the prisoner in a death cell. Some psychiatrists allege that the death fear (whether on the battlefield or in the death house) serves as an irrational surrogate for some other fear—such as castration. This over-simplified explanation does scant justice to the inescapable certainty shared by all, but anticipated only by man.

SELECTED PERSONAL AND FAMILY DATA ON 400 PSYCHIATRIC INPATIENTS

IAN GREGORY, M.D.¹

There are at least three types of information that may be provided by data such as those analyzed in the present study. *Firstly*, they may cast some light on the validity of clinical diagnosis in psychiatry—the extent to which such diagnoses represent valid distinctions between different categories of psychiatric patients. *Secondly*, they may constitute one approach to testing the etiological hypotheses that certain categories of psychiatric disorder are determined predominantly by hereditary endowment and that other categories are determined predominantly by environmental influences. *Thirdly*, they may reveal associations between objective criteria of environmental influence and various diagnostic categories, and hence may provide leads to further research regarding the nature and specificity of environmental influences in the etiology of different psychiatric disorders. It is nevertheless necessary to emphasize that the method of analysis employed here gives no indication of the relative contribution of hereditary and environmental factors in the overall determination of psychiatric disorders, but only on possible *differences* in the contribution of such factors to the etiology of specific syndromes based on clinical diagnosis.

The present author has recently discussed certain studies and viewpoints relating to the validity of clinical diagnosis in psychiatry(6). It may, however, be appropriate to review briefly the results of two such studies that have been reported. The first of these was undertaken in Massachusetts over 30 years ago and involved comparisons of the diagnoses made on the same patients when they were in Boston Psychopathic Hospital and when they were in various Massachusetts state hospitals. Such data were recorded for 1,177 patients, and the degree of diagnostic agreement (among 20 categories of diagnosis) was found to be

approximately 70%. Gruenberg has pointed out that the discrepancy between diagnoses on these patients was about the same order of magnitude as has been found between clinical diagnoses in medicine and autopsy findings(7). Another study along the same line was undertaken a few years ago by Norris(10), who compared the clinical diagnoses made on patients in psychiatric observation units in London, England, and subsequently following their admissions to mental hospitals. Her sample involved over 6,000 patients, and the overall agreement in diagnoses (among 13 diagnostic categories) amounted to approximately 60%. In view of such discrepancies, some psychiatrists have advocated a unitary concept of mental illness(9) according to which all mental illness represents a single abnormality, whose manifestations vary quantitatively rather than qualitatively, are all likely to be helped by the same kind of treatment, and do not differ essentially in their causation. The contrary viewpoint is that specificity in effective treatment, accurate knowledge of causation and logical preventive measures should be based on clarity of diagnostic criteria.

The validity of testing genetic hypotheses by searching for environmental factors has been pointed out by Penrose(11) who remarked,

Modern psychiatric teaching emphasizes environment from early infancy as a decisive factor in determining mental breakdown. Objective evidence for environmental factors is difficult to obtain but many obvious avenues for research have been neglected, such as the study of the effects of the birth order and of maternal age on psychotic reactions. Analysis of variation of abnormal mental traits within families and especially within sibships would prove of interest from the environmental standpoint. Not all investigations which set out to investigate genetical causes demonstrate that these are the most significant factors. Results which are largely negative from the genetical point of view are of special value because we can search with renewed zeal for environmental influences.

¹ Asst. Professor of Psychiatry and Coordinator of Undergraduate Education in Psychiatry, University of Minnesota Hospitals, Minneapolis, Minn.

McKeown and Record have since discussed maternal age and birth order as indices of environmental influence(8), and the present author has attempted to analyze data on these and other objective indices in the case of psychiatric patients(2-5).

Adler emphasized the unique position of the individual within his family of orientation, and made various assertions concerning the supposed vulnerability of certain ordinal positions(1). Numerous other authors added their own clinical impressions, and many unsuccessful attempts have been made to establish consistent statistical associations between ordinal position and temperamental characteristics or vulnerability to psychiatric disorder. However, the statistical problems involved have not always been recognized, and the interpretation of positive findings still remains in doubt. Sears has provided interesting data on differences in child training practices related to the sex and ordinal position of the children(12), but the significance of such findings in relation to adult psychiatric disorders has not been demonstrated. Similarly, differential patterns of childhood experiences, related to such objective events

as parental death or desertion, have not hitherto been found consistently correlated with the development in adult life of specific patterns of psychiatric disorders.

METHOD

In previous articles, the present author has reviewed a number of studies relating to parental deprivation, parental age, family size, birth order and ordinal position, among various groups of psychiatric patients; and has subjected to further analysis certain data previously recorded by other investigators(2, 3, 5). In another article, considerable data of this nature were abstracted from the hospital records of 1000 patients born during a 30-year period and admitted to a single mental hospital during a specified period of time. The age of these patients on admission was approximately 20 to 50 years, and they were divided into 10 diagnostic categories, comparisons being made between different diagnostic groups and, where possible, also the general population from which they were drawn. Since the data were obtained, however, from histories recorded routinely in hospital files shortly after the patient's admission to hospital by

TABLE 1
Diagnosis and Sex of 400 Psychiatric Admissions to University of Minnesota Hospitals

DIAGNOSIS	MALE	FEMALE	BOTH SEXES
Acute brain disorders	3	4	7
Chronic brain disorders	8	9	17
Mental deficiency	1	1	2
Involuntional psychotic reaction	4	6	10
Manic depressive reaction	6	12	18
Psychotic depressive reaction	7	15	22
Schizophrenic reaction, paranoid type	21	33	54
Schizophrenic reaction, other types	23	39	62
Paranoid reactions	2	3	5
Psychophysiologic disorders	2	4	6
Psychoneurotic depressive reaction	20	62	82
Psychoneuroses, other types	7	34	41
Sociopathic personality	19	9	28
Other personality disorders	13	35	48
Observation, psychiatric		4	4
All diagnoses	134	266	400

different members of the staff, it was inevitable that certain information recorded in many of the files would be absent from others. As was also inevitable in using this type of information, there were other items of interest that were recorded relatively infrequently.

For the purpose of the present investigation, therefore, it was decided to obtain selected personal and family data by means of special forms containing a standardized series of questions, to be answered in detail for as high a proportion as possible of a selected group of psychiatric patients. The group of patients selected for study were all those admitted to the adult psychiatric wards of the University of Minnesota Hospitals, and also assigned directly to the care of one of the first year residents in psychiatry under the supervision of a staff psychiatrist. During a period of almost two years, commencing in Oct. 1959, 449 such patients were admitted, and completed forms obtaining the necessary personal and family data were returned on 400 of these patients. The present article is concerned with an analysis of the data recorded on the 400 forms.

The clinical diagnoses on these patients conformed with the standard nomenclature, and were made by the psychiatric residents in consultation with supervising staff psychiatrists. The diagnoses were made at the time of discharge from hospital for all patients with the exception of those who were still on the psychiatric service at the termi-

nation of data collection. The sex distribution for 15 major categories of diagnoses is shown in Table 1.

In view of the small numbers of patients in certain categories, certain of these were combined for purposes of analysis, and the mean age on admission for 9 major diagnostic groups is shown in Table 2. It was further considered that the 2 smallest of the latter groups (brain disorders and mental deficiency, with 26 patients; and observation only, with 4 patients) would best be excluded from the final analysis, and the latter therefore involves only the 370 patients in the 7 remaining diagnostic groups.

In previous studies the present author has attempted to find deviations from statistical expectancy for selected characteristics (*e.g.*, parental deprivation, parental age, birth order, ordinal position) among patients with various psychiatric diagnoses. In the present study the numbers of patients in any major diagnostic category are too small to permit of this approach, and the reverse procedure has been applied—namely, testing for deviations in statistical expectancy of the 7 major diagnostic groups, among all patients having a given characteristic. The significance of deviations from statistical expectation has been measured by means of chi square and the results are presented in Table 3 (for primary characteristics of patients), Table 5 (for characteristics involving their parents) and Table 6 (for characteristics involving their sibships).

TABLE 2
Number of Patients and Mean Age on Admission,
Among Nine Diagnostic Groups (400 Patients)

DIAGNOSIS	NUMBER OF PATIENTS	MEAN AGE ON ADMISSION
Brain disorders and mental deficiency	26	48.6 years
Affective psychoses	50	45.9 years
Paranoid schizophrenia and paranoid states	59	35.4 years
Schizophrenia, other types	62	27.4 years
Neurotic depressive reaction	82	42.6 years
Neuroses, other types, and psychophysiologic disorders	41	33.7 years
Sociopathic personality	28	30.6 years
Other personality disorders	48	25.4 years
Observation only	4	23.2 years
All diagnoses	400	36.0 years

RESULTS

The primary characteristics of patients and their homogeneity among the 7 diagnostic groups are shown in Table 3. The most significant deviations from the mean (for all groups combined) were shown with respect to *age*, being related to the advanced age of many patients with affective psychoses and neurotic depressive reactions, and the youthfulness of many patients with schizophrenia (other types than paranoid) and personality disorders (other than sociopathic). There was also a significant deviation from homogeneity with respect to *sex* distribution, which was almost entirely re-

the two youngest groups, and under-represented in the two oldest groups. In the case of *divorced or separated* patients among those who had ever been married, sociopathic personality was over-represented, whereas neuroses (types other than neurotic depressive reaction) were under-represented.

In order to determine the extent to which the lack of homogeneity with respect to the preceding characteristics might be related to the differential age distribution of patients in various diagnostic categories, *rank order correlation coefficients* were calculated between the mean age on admission among

TABLE 3
Characteristics of Patients and Their Homogeneity Among
Seven Diagnostic Groups (370 Patients)

CHARACTERISTICS OF PATIENTS	NUMBER OF PATIENTS WITH CHAR- ACTERISTIC	CHI SQUARE	DEGREES OF FREEDOM	STATISTICAL SIGNIFICANCE
Age (40 years and over)	124	74.85	6	$p < 0.001$
Sex (Male)	124	22.42	6	$p < 0.01$
Foreign born	22	9.55	3	$p < 0.05$
Education (8 years or less)	68	30.91	6	$p < 0.001$
Education (one or more years of college)	99	15.42	6	$p < 0.02$
Marital status (single)	125	53.33	6	$p < 0.001$
Marital status (divorced or separated, among ever-married)	44	16.73	6	$p < 0.02$

lated to reversal of the prevailing sex ratio (approximately two females to one male) in the case of sociopathic personality (with twice as many males as females). The total number of *foreign born* patients was small, and necessitated combined diagnostic categories, the probable significance of the results being attributable to an excess of observed over expected number of foreign born patients with affective psychoses. The significant deviation from expectation with respect to *education of 8 years or less* was related largely to an excess of patients with affective psychoses and neurotic depressive reactions (the two oldest groups). Among those with *one or more years of college education*, in this particular sample, there was a moderate excess of observed over expected patients with paranoid schizophrenia, other types of schizophrenia and sociopathic personality. With respect to *marital status*, *single* patients were over-represented among

different diagnostic groups and the percentage of patients in each diagnostic group having the characteristics shown in Table 3. These rank order correlation coefficients and their statistical significance are shown in Table 4, from which it is evident that education of 8 years or less was strongly positively correlated with age on admission, whereas single marital status was strongly negatively correlated with age on admission. Some of the other correlations with mean age on admission are suggestive, although they are much less marked in degree and not statistically significant.

Selected characteristics involving parents and their homogeneity among the 7 diagnostic groups, are presented in Table 5. In only two instances were there overall deviations from expectation which reached the level of probable statistical significance. Among *native born patients having one or both parents foreign born*, there was an ex-

TABLE 4
Rank Order Correlations Between Mean Age on Admission and Percentages of
Patients with Characteristics Shown in Table 3

CHARACTERISTIC	SPEARMAN'S RANK CORRELATION COEFFICIENT WITH MEAN AGE ON ADMISSION	STATISTICAL SIGNIFICANCE
Sex (male)	+0.38	N.S.
Foreign born	+0.37	N.S.
Education (8 years or less)	+0.92	$p < 0.001$
Education (one or more years of college)	-0.55	N.S.
Marital status (single)	-0.92	$p < 0.001$
Marital status (divorced or separated, among ever-married)	+0.40	N.S.

cess of observed over expected numbers of patients with affective psychoses and neurotic depressive reactions, as compared with a deficit of observed numbers of patients with schizophrenia (types other than paranoid) and personality disorders (other than sociopathic). The rank correlation coefficient with mean age on admission was +0.75 and reached the level of probable significance ($p < 0.05$), which would appear to reflect merely the higher rate of immigration around the turn of the century than

a generation later. On the other hand, the deviations from expectation of *patients with a history of parental suicide or admission to mental hospital* appear more directly related to the diagnoses of these patients. (The rank order correlation with mean age on admission being +0.18, and not significant.) There was an excess of observed over expected numbers of patients having a history of parental suicide or admission to mental hospital for schizophrenia (types other than paranoid) and for neurotic depressive re-

TABLE 5
Characteristics Involving Parents, and Their Homogeneity
Among Seven Diagnostic Groups (370 Patients)

CHARACTERISTICS INVOLVING PARENTS	NUMBER OF PATIENTS WITH CHAR- ACTERISTIC	CHI- SQUARE	DEGREES OF FREEDOM	STATISTICAL SIGNIFICANCE
One or both parents foreign born (among native born patients)	88	14.49	6	$p < 0.05$
Native born fathers with 8th grade education or less	125	8.85	6	N.S.
Fathers having less education than mothers	74	2.55	6	N.S.
One or both parents over age of 40 years at birth of patient	77	4.92	6	N.S.
Mothers older than fathers	31	5.33	6	N.S.
One or both parents committed suicide or admitted to mental hospital	40	12.67	5	$p < 0.05$
Father recorded as alcoholic	31	3.99	5	N.S.
One or both parents died before patient aged 10 years	27	5.13	5	N.S.
Other permanent separations from one or both parents before patient aged 10 years	34	3.36	5	N.S.
Father lost by death or other permanent separation before patient aged 10 years	49	6.51	6	N.S.
Mother lost by death or other permanent separation before patient aged 10 years	22	6.16	4	N.S.

action, as compared with a deficit of observed numbers of patients with other types of neuroses and personality disorders (other than sociopathic).

Selected characteristics involving sibships, and their homogeneity among the 7 diagnostic groups are shown in Table 6. On examination of this table, it may be seen that deviations from expectation only approached or reached probable statistical significance with respect to two of the characteristics studied. Both of these findings related to the *birth interval* between the patient and the sibling immediately preceding or following him, and both involve birth intervals of less than two years between the patient and this sibling. In the case of patients having a sibling less than two years *older* than themselves, there was an excess of patients with paranoid schizophrenia. Among patients having a sibling less than two years *younger* than themselves, there was an excess of patients with

sociopathic personality and other personality disorders.

SUMMARY AND CONCLUSIONS

The type of data analyzed in the present study may provide evidence concerning the validity of clinical diagnosis in psychiatry, a differential contribution of hereditary and environmental factors in the etiology of specific diagnoses, and association between objective criteria of environmental influence and various diagnostic categories.

Selected personal and family data were recorded soon after admission on 400 out of 449 consecutive psychiatric patients admitted to the University of Minnesota Hospitals and assigned to the care of residents under the supervision of a staff psychiatrist. The data on 30 patients (with diagnoses of organic brain syndromes, mental deficiency, or observation only) were discarded, and the data on the remaining 370 patients were divided into 7 major categories for purposes

TABLE 6
Characteristics Involving Sibships, and Their Homogeneity
Among Seven Diagnostic Groups (370 Patients)

CHARACTERISTICS INVOLVING SIBSHIPS	NUMBER OF PATIENTS WITH CHAR- ACTERISTICS	CHI- SQUARE	DEGREES OF FREEDOM	STATISTICAL SIGNIFICANCE
No siblings of either sex (patient an only child)	22	1.39	4	N.S.
No siblings of the same sex (one or more of the opposite sex)	84	8.17	6	N.S.
No siblings of the opposite sex (one or more of the same sex)	67	2.14	6	N.S.
No older siblings (patient the eldest)	86	4.47	6	N.S.
No younger siblings (patient the youngest)	72	2.13	6	N.S.
Patient immediately preceded and followed by siblings of same sex	36	1.70	6	N.S.
Patient immediately preceded by sibling of same sex and followed by sibling of opposite sex	48	3.56	6	N.S.
Patient immediately preceded by sibling of opposite sex and followed by sibling of same sex	43	5.03	6	N.S.
Patient immediately preceded and followed by siblings of opposite sex	57	0.83	6	N.S.
Immediately preceding sibling more than 5 years older than patient	41	5.42	6	N.S.
Immediately preceding sibling less than 2 years older than patient	55	13.82	6	$p < 0.05$
Immediately following sibling more than 5 years younger than patient	46	1.22	6	N.S.
Immediately following sibling less than 2 years younger than patient	67	11.69	6	$p < 0.10$

of analysis.

Primary characteristics of patients (particularly age, sex, education and marital status) showed a significant lack of homogeneity among the 7 diagnostic groups, giving some support to the validity of clinical diagnosis in psychiatry. At least it is evident that these diagnostic groups differ from each other significantly with respect to these characteristics, though it remains questionable to what extent they differ in their manifestations, etiology or response to treatment.

Most of the selected characteristics involving parents and sibships failed to show deviations from homogeneity among the 7 diagnostic groups, and hence provided little evidence concerning the influence of specific etiological factors in the development of specific diagnostic syndromes.

In patients with a history of parental suicide or admission to mental hospital, certain diagnoses were represented more or less frequently than expected on a random basis. However, this association between patient diagnosis and parental psychopathology may be related to either genetic or environmental factors.

The increased frequencies of certain diagnoses among patients with intervals of less than two years between themselves and their preceding or following siblings are suggestive of environmental influences in

the etiology of the diagnostic groups involved, but the findings in this relatively small and heterogeneous sample must be regarded as very tentative.

THE NATURE OF PSYCHIATRIC RESEARCH WITH REFLECTIONS ON THE RESEARCH OF FREUD AND HUGHLINGS JACKSON AND ON THE LIMITATIONS OF STATISTICS

MAX LEVIN, M.D.¹

Hamburg's recent article(1) on the training of the psychiatrist has prompted the following reflections. While his article is stimulating and constructive, there are intimations in it on the nature of research that call for comment.

In describing the residency training program in a major teaching center, Hamburg tells of the effort made to arouse an interest in research. The effort begins in the first year of the residency, with seminars on research problems and techniques. Referring to the topics presented in these seminars, Hamburg says :

The papers taken up during the first few weeks of the seminar dealt with relatively familiar problems, highly relevant to the residents' current activities. For example, since the residents began their clinical training with work on the inpatient units, initial papers typically dealt with problems of schizophrenia—for example, family relationships in schizophrenia, psychotherapy with schizophrenics.

In the first few weeks of a training program the natural impulse would be to assign problems of a simple and elementary kind, and it would seem that Hamburg believes that "family relations in schizophrenia" and "psychotherapy with schizophrenics" fall into this category. But these problems are far from simple and easy. Indeed, one can scarcely think of problems for research that are more complex and tricky.

If it is true that Hamburg judges these problems to be simple, what is the basis of his judgment? Perhaps it is, in part, their amenability to statistical treatment. You take 50 young schizophrenics and a control group of 50 healthy college students, and you see, for example, which group has the higher incidence of unloving mothers. But in psychiatric research we must not exag-

gerate the value of statistics.

It is widely believed that if an investigation lends itself to statistical treatment, it is "scientific" and "objective." Otherwise it is "subjective" and relatively worthless. In all candor I must say that our colleagues in psychology are inclined to this view. Many of them hold that research in problems of the mind devolves upon them rather than psychiatrists, for they are trained in statistics, whereas physicians have only an elementary knowledge of this subject, if any. But this conception of the nature of research is much too narrow. In the entire history of psychology the finest research was that done by Freud, and in all his work there is not a single graph or table, and one looks in vain for a reference to chi square.

At the risk of oversimplification I would suggest that psychiatric research falls into two categories: the fact gathering type of study that lends itself to statistical treatment, and the more complex type of study that seeks to *explain* mental phenomena.

Many studies in the first category, I submit, are not really research. They only wear the facade of research. They are reminiscent of Madison Avenue, where an investigator is said to be doing "research" when he rings the doorbells of a thousand housewives to ask which soap they prefer. Of course, this comment does not apply to studies in such fields as biochemistry, where the quantitative approach is a necessity. It would be impossible to explore the metabolism of serotonin without a quantitative orientation. But in the field of psychology the quantitative approach is not always fruitful. Indeed the history of psychology shows that its greatest achievements came from flashes of insight, comparable to the intuition of the creative artist. Freud's achievements did not require the use of an adding machine or a computer. They sprang rather from the reflections of a genius, like the inspirations that produced

¹ Section on Neurology, Dept. of Medicine, The New York Medical College, New York, N. Y.

the symphonies of Beethoven.

Newsweek magazine on May 22, 1961, carried an item that has some bearing on the applicability of statistics to the more complex problems of life. A professor of psychology died, leaving two young unmarried sons. An authority on psychometrics, he believed in the prognostic value of standardized tests in regard to success in marriage. In his will he urged his sons and their future brides to appear before a team of psychologists for a battery of tests. He had worked out a formula leading to a score in terms of so many points above or below "E" (for eugenics). The will provided that the young couples be awarded \$400 for each point scored above E and penalized the same for each point below E. The motive is praiseworthy, but its expression is stultifying, for we may imagine the following possibility. A son falls in love with a Wellesley graduate *summa cum laude* who is working for her Ph.D. in physics. The young woman, who is not lacking in brains, asks herself, "How much does my young man love me for myself alone? Is he influenced at all by the number of points I can score above E?" The doubt created in her mind would never be compensated for by \$400, nor by any multiple of \$400. As the Preacher pointed out in Ecclesiastes, there is a time and place for everything. Statistics have their value but only in their proper place. A battery of psychometric tests that is a powerful tool in the hands of a school guidance counselor may be useless in the hands of a lover. Marriage, like all of life, is a gamble, and the biggest battery of tests given by a board of experts cannot make it less so.

The multiplication of "research" projects that can yield nothing but a confirmation of the obvious is a growing scandal. I have before me a study of the reactions of Negro children to race and color. The investigators presented the child with dolls that were identical except for color. Some of the dolls were white with blond hair, while the others were brown with black hair. The child was asked to select "the doll you like best," "the doll that looks nice," "the doll that looks bad," "the doll that looks like a white child," "the doll that looks

like a colored child," "the doll that looks like you." The test was given to many Negro children in a Southern state and a Northern state. The ages were from three to seven. The article has numerous statistical tables, correlating the responses with age, location (North or South), color of child (light, medium or dark), *etc.* Not surprisingly, the children tended to prefer the white doll to the colored doll. In response to the request to select "the doll that looks like you," the percentage of correct responses (the brown doll) increased with age: the older the child, the more likely is he to know he is colored. But what man with eyes to see and ears to hear must undertake a research like this to discover that Negro children, as they grow up, become conscious of their color?

A word about the moral aspect of the study. The authors stress the quantitative nature of the study, but (rather apologetically) they also present "some qualitative data." We read that in giving their reasons for preferring the white doll, the children would explain, "'cause he's pretty, 'cause he's white," while they rejected the brown doll "'cause he's ugly, he's got black on him." A 5-year-old dark child explained his identification with the brown doll by saying, "I burned my face and made it spoil." A 7-year-old light child said he is really white, but "I look brown because I got a suntan in the summer." Some children who were relaxed at the beginning of the test "broke down and cried during the latter part when they were required to make self-identifications. Indeed, two children ran out of the room, inconsolable, convulsed in tears." One is appalled by the unconscious brutality of intelligent and educated men who subjected Negro children of tender years to mental torture in an investigation which, as they should have foreseen, would add nothing to existing knowledge.

I have mentioned the work of Freud as an example of research *par excellence*. Freud needs no "plug" from me, and I shall instead proceed to some equally outstanding psychiatric research that has been all but forgotten, the work of Hughlings Jackson. Jackson is remembered for his work on epilepsy and aphasia, but not many are aware of his investigations into the mind.

I shall consider one example from the work of this man, who, it seems to me, was the most realistic of all those who have tackled the mind-brain problem (8).

The Tendency in Delirium to Mistake the Unfamiliar for the Familiar. Observations on delirium are scattered throughout Jackson's papers, and it is evident that this condition interested him deeply. He showed how the phenomena of delirium fit in with his conception of the organization and function of the nervous system (5, 7).

Jackson believed that the basic design of the nervous system is the same from bottom to top, though, to be sure, as one passes from lower to higher levels there is an increase in complexity. The same principles of function apply to all levels.

Jackson paid much attention to a principle he called "reduction to a more automatic condition." Lower levels are more highly organized and function more automatically than higher levels. When centers on a higher level are paralyzed, the responses they normally mediate may be mediated, after a fashion, by lower centers instead; that is to say, there is "reduction to a more automatic condition." Higher centers being paralyzed, the nervous system tries to make do with what remains, like a man with crippled legs who crawls when he cannot walk.

In his study of delirium Jackson made the observation that the patient tends to mistake the unfamiliar for the familiar. The classic example is the man in the hospital who thinks he is at home and mistakes the nurse for his wife. Jackson showed that this is a manifestation of reduction to a more automatic condition. Elsewhere (5) I have considered in detail his presentation of this matter, with extensive quotations from his papers.

This tendency to mistake the unfamiliar for the familiar is by no means confined to delirium. In delirium we see in grotesquely exaggerated form a tendency found in normal people as well. It is never entirely easy to recognize the new. In a novel situation the instinctive tendency is to overlook the novelty and to think instead that the situation is like those one has met before. There is a lot of good physiology and psychology in the story of the small boy who thought

that the Lord's Prayer begins with these words: "Our Father who art in Heaven, *Harold* be Thy name." And there is the little Puerto Rican boy in New York who was learning the National Anthem and was heard to sing: "José, can you see?"

Pertinent here is a remarkable observation that Kubie (4) made in Penfield's operating room. The patient was a farm girl about to undergo extirpation of an epileptogenous focus in the temporal lobe. Kubie was under the drapes with his recording equipment, and he showed her a series of pictures of simple objects and asked her to name them.

She did this quite readily until Dr. Penfield stimulated the area in the lobe which caused an arrest of speech. This occurred just as she had been shown the drawing of a human hand. At the moment of electrical stimulation all speech ceased as though frozen into immobility. It was like watching a motion picture brought to a sudden halt. Then as the current was turned off she began to make mouthing movements and then slowly and hesitatingly said in sequence: "five, five . . . five horses . . . five horses . . . five pigs . . . five pigs . . . five fingers . . . hand."

Confronted with the picture of a hand as function slowly returned to her speech areas, the patient was understandably obsessed with the number five. But why did she say five *horses* and five *pigs*? Clearly it was because, as a farm girl, she habitually thought in these terms. Had she been a pianist, her response might have been in terms of finger action at the keyboard. Or if the patient had been an Army officer stationed in Washington, he might have thought of the Pentagon.

In demonstrating, first, that the delirious patient tends to mistake the unfamiliar for the familiar, and, second, that this tendency is understandable as a manifestation of reduction to a more automatic condition, Jackson may be credited with an achievement that can serve as a model of psychiatric research of the highest order. It is "pure" research, with no practical value. It will not help us to cure a patient faster, or to localize a lesion. But it is entitled to be called research because it helps us to understand how the brain carries out its function of enabling us to appreciate reality.

It is remarkable that Jackson discovered the existence of this tendency, a clinical fact that eluded the eye of Kraepelin, the prince of descriptive psychiatry of a later generation. Jackson was no psychiatrist, but he had an inquiring mind. He spoke of the highest cerebral centers as "the organ of mind," and a thinking disturbance challenged him to determine the kind of cerebral dysfunction that would account for it. He was not content to rest on the proposition, "The patient is disoriented; he mistakes the nurse for his wife; we may therefore say he is delirious." He asked—and answered—the question: "Why does he mistake the unfamiliar for the familiar? What kind of physiological loss would account for it?"

Loss of the Ability to Name the Physician's Occupation on Command with Retention of the Ability to Name it Spontaneously. We now proceed to another observation in delirium, one of my own. It is brought up here not only because (at least in my opinion) it is of some interest and value, but also because the observation, or rather the way it came to be made, is useful in a consideration of methodology in psychiatric research.

In delirium the patient is disoriented, and if you ask him your occupation he may be unable to answer correctly, saying either he does not know or else giving a wrong answer. But then a striking thing happens: in talking to you he may spontaneously address you correctly by title, as when he says "Yes, Doctor" or "No, Doctor" or when he replies to some friendly remark, "Thank you, Doctor." Should you again ask him your occupation, he may again fail, even though he has addressed you by title only a moment before. I have often made this experiment: when the patient has addressed me by title, I ask him my occupation and he gives an incorrect answer; we then continue talking until the next time he addresses me by title, whereupon I again ask him my occupation and again he answers incorrectly. This may occur over and over in the same interview.

Sometimes the patient addresses you as Doctor *in the very sentence* in which he tries unsuccessfully to name your occupation (4, 6). Thus a woman in a bromide

delirium, when asked my occupation, replied, "I wouldn't know, Doctor, is it painting and decorating?"

This phenomenon is not a capricious accident. It is identical in principle with a phenomenon in motor aphasia to which Jackson paid close attention (4, 6). He emphasized that in aphasia it is not words that are lost, but rather the use of words in specific contexts. His favorite example was the patient who cannot say "No" on command, yet he can say it in reply to a question that calls for a negative answer, and, better still, he can shout it under emotional stress, as when he sees his child creeping too close to the fire. Jackson gave this as an example of reduction to a more automatic condition. Shouting "No" under emotional stress is highly automatic. When a man shouts to a child in danger, he does not have to think of his words; they come to his tongue automatically. By contrast, to say "No" on command is highly voluntary: the utterance is a studied and calculated act.

Similarly in delirium, when you ask the patient to name your occupation, you are testing a voluntary function. He must *think* in order to answer. But when he spontaneously addresses you as "Doctor," he does it without thinking. His act is automatic. He doesn't *know* he is addressing you as "Doctor," for he may do so many times in an interview in which repeatedly and invariably he fails to name your occupation when asked.

The parallel even extends to those instances in which the patient addresses you as "Doctor" in the very sentence in which he tries unsuccessfully to name your occupation. The aphasic patient, striving in vain to say "No" on command, may at last cry out in despair, "No, I can't say it."

Clearly there is a precise parallel between the phenomenon in delirium and the one in aphasia. They both are manifestations of reduction to a more automatic condition. In aphasia, as Jackson emphasized, it is not words that are lost, but the ability to use words in particular situations. The patient has not lost the mechanism for the word but the mechanism that enables him to say it *voluntarily*. He can still say it automatically. Correspondingly, in delirium the patient has lost, not the concept "Doc-

tor," but only the capacity to name your occupation when you ask him to, when he must *think* what it is. He recognizes you as a doctor automatically—so long as he does not *try* to. The moment you ask him to try to recognize you, he fails.

The observation in delirium was made in the course of a study of the bromide psychoses, in which I would sit down with the patient, not to "examine" him, but simply to talk to him, to try to learn how he thinks. It is here that the matter of methodology comes up. Here is a typical situation. A patient is admitted to the psychiatric ward, and the resident comes to "do a mental status" on him. With the outline before him, he asks scores of questions—the date, the name of the President, and so on. When he is finished, he gathers up his notes with a sigh of relief and wonders which of his many chores to turn to next. He feels he need no longer spend much time with the patient. He has "finished the mental status." From now on he must note only the changes that may occur—and here the nurses can help him. I submit that this is not the best way for a young physician to learn the psychoses. He will not learn schizophrenia by "doing a mental status" on a dozen—or a hundred—cases. What he must do is talk to the patients often and at length, without limiting himself to a standard list of questions. In the course of a routine mental status you are not likely to observe that the delirious patient can address you spontaneously by title though he cannot name your occupation. But if you talk to him freely and often, you will sooner or later make this observation.

If I were preparing a program to stimulate an interest in research in young residents, I would consider the following suggestion: Spend as much time as you can with the patients on the ward. Watch them work and play. Sit down and talk to them, over and beyond the routine mental status. Talk to them about baseball, books, jobs, anything under the sun. You want to learn how the psychotic patient thinks, how his thinking differs from yours.

The reader may object: This is all well and good, but it is not research. It is merely one way for the resident to learn the rudiments of descriptive psychiatry. Research

means adding to the store of knowledge, not just acquiring that which already exists.

Implicit in this objection is the belief that descriptive psychiatry is already a closed subject. I prefer to believe otherwise. Surely it is not possible that we already know all there is to know of the manifestations of the mind and its disorders, a field of infinite complexity and diversity. Kraepelin and Bleuler have by no means said the last word. It was not until the 1930's that the observation was made that the delirious patient can address you as "Doctor" when he cannot name your occupation.

I conclude with a personal note. In 1931, before the appearance of *The Selected Writings of John Hughlings Jackson*, volumes I and II of *Brain* fell into my hands. Curious to see what neurologists were doing in those days, I browsed through the volumes and came upon Jackson's article (in three sections) "On Affections of Speech from Disease of the Brain." It was the first article of his I had ever seen, and I was enchanted by the clarity of his exposition of a complex subject. Readers justly complain of his obscure writing, for he lacked the literary grace of a Sherrington. But no one can complain of his thinking. Jackson was no giant of the pen, but he was a giant of the intellect. It was soon afterward that a delirious patient who was completely disoriented addressed me spontaneously as "Doctor." Immediately there flashed through my mind the thought, "Amazing: this is exactly what Jackson emphasized in aphasia, where the patient can say 'No' spontaneously but not voluntarily." I wondered, "How many times did this observation in delirium come my way and I failed to notice it because it had no meaning for me?" I will never know. The soil must be prepared before the seed can take root.

SUMMARY

Psychiatric research, in the best sense of the term, means the *explanation* of behavior. The mere gathering of facts, which are then treated statistically, is not necessarily the highest type of research. Freud's work and the work of Hughlings Jackson on the mind-brain problem are held up as examples of research of the highest quality, with specific reference to Jackson's demon-

stration of the value in delirium of his concept of "reduction to a more automatic condition."

SOCIETY AND THE SOCIOPATH¹

MAXWELL JONES, M.D.²

The difficulty of separating moral from strictly medical judgments is one of the most difficult problems we have to face in psychiatry. In the evidence admitted on the behalf of the Institute for the Study of the Treatment of Delinquency to the Wolfenden Committee on homosexual offenses and prostitution, the following statement is found: "To the psychiatrist, the problem of homosexuality raises no question of criminality unless the sexual deviation is associated with acts of violence, assault or seduction of minors"(1). Commenting on this statement, Barbara Wootton states, "Psychiatrists generally, and the particular group of psychiatrists in whose name this evidence was drawn up, are as much entitled to their personal opinion as is anybody else. They may, if they wish, dislike violence or assaults upon minors while raising no objection to homosexual acts between consenting adults or at least deprecating the prohibition of these by the criminal law. But in what sense such views can claim to be medically established is far from clear"(2). The same difficulty applies in the whole field of sociopathy. Freedman says that the psychiatrist "talks the language of the scientific method and has a professional need to consider his social preference as having resulted from scientific observation. He is in danger of replacing the semantics of social morality with that of psychological morality without changing the substance." (3). The fact would seem to be that if psychiatry is to play a useful part in the field of sociopathy, it has to give up purely medical concepts like sickness, and moral judgments like sickness or sin, and concentrate on finding a role in conjunction with the social sciences and penology. Public health was once primarily concerned with the epidemiology of infectious diseases and has now moved much closer to the field of social

medicine. In the same way, it would seem that psychiatry has to concern itself with the problems of the sociopath, the alcoholic, the criminal, the work shy and so on but cannot hope to do this adequately unless there is the closest liaison with the other disciplines. Such a transition is, of course, already apparent in many areas and the schools of public health, such as Harvard and Johns Hopkins, have gone a long way to bring about such an interdisciplinary training for psychiatrists.

In Britain, the new Mental Health Bill(4) represents a bold step in the direction of social planning. In it, psychopathic disorder is described as "persistent disorder of personality, whether or not accompanied by subnormality of intelligence, which results in abnormally aggressive or seriously irresponsible conduct on the part of the patient and requires or is susceptible to medical treatment." This description will satisfy no one but is at least an attempt at a working definition. The British plan to establish special centers for the treatment of character disorders and referrals from the psychiatric clinics, from the courts and from the prisons can be made to these centers. By implication they accept the fact that the sociopath requires something in addition to the traditional mental hospital and penal institution. It is anticipated that these treatment centers will have both open and closed wards and will be available to both voluntary and committed patients. In Britain, the new Bill allows for the compulsory detention of a sociopath in a psychiatric hospital provided he be under the age of 21. However admission for observation for a period not exceeding 28 days can be arranged for a patient of any age. Both forms of compulsion require two medical certificates and no legal formality. As yet, very little use is being made of these compulsory procedures. The Royal Commission report(5) pointed out, "If the psychopathic patients are subjected to special forms of compulsion on grounds of abnormality, which is evidenced mainly by their be-

¹ Read at the 118th annual meeting of The American Psychiatric Association, Toronto, Canada, May 7-11, 1962.

² Director, Education and Research, Oregon State Hospital, Salem, Ore.

havior, this is almost equivalent to the creation of a special quasicriminal code for them alone."

So far, only the special treatment unit at Henderson Hospital, formerly called the Social Rehabilitation Unit, Belmont Hospital(6), is in being, but several other special centers for the treatment of psychopaths are planned. It will be interesting to see what location will be chosen for these new units. If they are attached to psychiatric hospitals, there would be obvious gains in economy and in sharing specialist medical services. More important is their attachment to an ongoing psychiatric service with its established traditions, its own catchment area, and its contact with the local authorities, general practitioners, and others. Moreover, the psychiatric hospital would be already familiar in the neighborhood and the addition of a psychopathic unit would be less challenging (and anxiety provoking) than a new establishment in a new environment solely for the treatment of sociopaths.

On the negative side, however, the establishment of a unit of this kind in an existing mental hospital could create a difficult minority problem. Psychopathic or sociopathic units tend to be seen as privileged, "different," and dangerous. Moreover, the treatment needs of sociopaths are, according to many psychiatrists, quite different to those of the ordinary psychotic in a mental hospital and call for another kind of social organization. Two separate treatment ideologies within the same hospital tend to create difficulties. The alternative is to have separate psychopathic hospitals which develop their therapeutic cultures unhindered by the established treatment ideology and mores of a parent hospital. Such an arrangement, however, would tend to isolate the sociopathic unit from the general body of psychiatry and create a state of affairs not unlike that which has happened in the case of mental retardation. The important point is that the British have embarked on a course of action which means the bringing together of sociopaths from both psychiatric and legal referral channels and indicating that their requirements call for further research and special centers to meet the particular needs of this type of

patient. It remains to be seen what will actually be accomplished.

In the U. S., the picture is even less clear. Various states have their own particular arrangements and in some states, special psychopathic laws allow for the commitment through legal channels of sociopaths to hospitals which are designed for their treatment. Atascadero State Hospital in California is an example of a hospital where the referrals are largely labeled sexual psychopaths. Commitment under the existing laws to this institution represents, in a sense, an indeterminate sentence and it seems that the sociopath would frequently prefer to be sent to prison where he would be given a more definitive sentence. In the main, however, it seems that the severe sociopath in the U. S. has to break the law in order to come under some kind of social system where help may (hopefully) be forthcoming. It is interesting to note that the Final Report of the Joint Commission on Mental Illness and Health(7) makes a strong appeal for improved treatment for the psychotic but makes relatively little of the problem of the character disorder. In the summary of their recommendations for a National Mental Health Program, they state,

In the absence of more specific and definite scientific evidence of the causes of mental illnesses, psychiatry and the allied mental health professions should adopt and practice a broad, liberal philosophy of what constitutes and who can do treatment within the framework of their hospitals, clinics, or other professional service agencies, particularly in relationship to persons with psychosis or severe personality or character disorders that incapacitate them for work, family life, and everyday activity.

However, at no point does the Report really come to grips with the social problem of the character disorder. In relatively few states has any serious attempt been made to isolate the problem, either in the departments of mental hygiene or in the penal system. One of the most interesting developments is in the Department of Corrections in California where several active attempts are made to treat sociopaths and drug addicts under "living group" condi-

tions. In these living groups, communities of 60 to 80 men are brought together and live in the same quarters, either within the penal institution itself or in a forestry camp. These living groups are run on therapeutic community lines with daily meetings of the entire inmate and staff population. Behavior is talked about freely and free expression of feelings is encouraged. A large degree of responsibility is put in the hands of the inmates and decision-making on matters of considerable import is shared with both the inmates and staff. In one unit, the inmates all work in the laundry, and the problems which develop in the work situation are fed back to the daily community meetings. Another experimental treatment unit involving a forestry camp also has daily meetings of inmates and staff. The forestry personnel, and the correctional and custody staff all participate in the daily meetings where work problems as well as the other emotional difficulties are discussed. The new Narcotics Bill in California will allow any addict to go to any doctor, or to the police, or to the courts and ask to be committed to the new rehabilitation center, which is being built at Chino. Male, female and youth authority drug addicts will all be housed in the same treatment center. In this center, custody and treatment functions will be fused and units of 60 drug addicts will be in the charge of a social worker. It is planned that these units will carry out a form of group therapy on a daily basis and it is probable that there will be mixed groups, with male and female drug addicts coming together in the same group.

The Department of Corrections is developing a treatment which is not slavishly copying the psychiatrist's concept of psychotherapy and which has as its main purpose the modification of antisocial attitudes. They have psychiatric consultants but have tended to blend their skills with those of the social scientists. In addition, a rigorous research program is attempting to assess the comparative merits of individual and group counseling, group treatment, and community treatment with as many as 60 to 80 inmates involved in one meeting. This is, I think, a more extensive study of treatment methods than any going on in mental

health at the present time. Moreover, as more than 80% of their inmates are put on parole on leaving their institutions, a very adequate follow-up study is possible.

Extensive statistical research into parole violation rates has resulted in the development of a "base expectancy score" which can predict with considerable accuracy the probable parole outcome of inmates on release from prison. All intakes to the Department of Corrections are now being given this base expectancy score and this can help to indicate the optimal length of stay in an institution, which may in certain cases be shortened if the base expectancy score is high. This amounts to letting the inmate serve part of his sentence in the general community supervised by a parole officer. I wish that in the field of mental health we had something equivalent which would allow us to decide on the prognosis and optimal time for discharge in many of our sociopathic and mental patients.

Douglas Grant, head of research in the Department of Corrections in California, is also working on a social maturity scale(8). This is an interesting attempt to introduce a classification system which promises to be more appropriate for a prison population than any psychiatric classification yet devised. A scale on which maturity judgments are based is derived from a theoretical quantification of the individual's capacity to form relationships with other people. This theory describes 7 maturity, or integration, levels which represent successive stages of growth in the capacity to perceive self and the environment without distortion. This implies an increasing capacity to form social relationships and to integrate more realistically and effectively with one's environment. They are attempting to correlate the inmates' social maturity level with the effectiveness of different forms of treatment and also with the social maturity level of the staff who are carrying out the treatment. This links up with the fascinating and as yet little studied problem of the competence of the average, middle class psychiatrist or social scientist to understand and communicate effectively with patients coming from the lower socio-economic groups.

The Department of Corrections is also

reaching out into the community in various ways. Family groups are being encouraged in some areas and several outpatient services are being developed where inmates can look for further help on discharge. Moreover, the parole officers are in a position to offer continued treatment and, under certain circumstances, recommend return to an institution for further supervision and treatment. At least one halfway house is being planned and the youth authority is attempting a community treatment project in which a group of social workers are given a small caseload of 8 parolees and are carrying out what amounts to very careful, individual casework supervision, working with schools and with families, and at the same time acting as parole agents.

Projects such as these and the work going on at Highfields in New Jersey(9) and Pinehills at Provo(10) in Utah indicate that the major initiative and progress in the field of the treatment of character disorders seems to be going on outside the body of psychiatry. It would seem to me that no one group can possibly tackle this problem effectively without using all the available resources from other disciplines. As things are, the majority of sociopaths under treatment are probably to be found in the state hospitals where little or nothing of a constructive or planned program is available. Our social workers are in short supply and in any case, they appear to have lost their skills in supporting and treating patients in the community and have tended to focus on individual casework in their offices. With the opening up of state hospitals, the increasing number of patients coming for treatment voluntarily and the increasing infiltration of the community, one can hope that the sociopath will be able to get help at an early stage of his career. There would seem to be a very good case for the establishment of some pilot units in state hospitals where cases can be admitted voluntarily or referred for treatment from the courts or from prison. Units of this kind would be expensive and would probably require a more generous staff: patient ratio than would the rest of the hospital. Moreover, the training and social organization in these units would probably be different to the rest of the hospital. It is only by

establishing such units under optimal conditions that we can get some awareness of the relative advantages of treating many of these individuals in state hospitals as opposed to a prison. Alternatively, some separate treatment units which are perceived as neither mental hospitals nor correctional penal institutions might be tried and compared with the more orthodox treatment methods. The fact is, of course, that until psychiatrists really feel that this undertaking is worth while, nothing very much will happen. My own experience would lead me to think that the sociopath can be helped, provided one establishes realistic and modest treatment goals. It is my belief that the majority of character disorders can be helped to modify their social attitudes and in some cases real personality change may be effected. With a wide social approach involving families in the treatment program, it seems that a great deal could be hoped for in the field of preventive psychiatry. Certainly, something must be done to try to prevent the vicious cycle of sociopaths drifting into "need fit" marriages and producing sociopathic children.

CONCLUSION

It would seem that we as psychiatrists have to clarify our thinking on the moral issues involved in sociopathy and come out strongly in favor of treatment for those cases, and I think they represent the overwhelming majority, where such an approach can help. If we take this stand then we must be prepared to carry out such a plan. Psychiatrists must believe in the efficacy of treatment and be prepared to help patients in outpatient clinics, hospitals, prisons, or special units established for this type of case. So far the moralistic attitude of the profession to this type of case has been one of the many factors hindering the development of adequate treatment facilities.

There would also seem to be a need for a multidisciplinary approach as psychiatry is often largely unaware of the developments in other fields such as correctional work and the theoretical and applied approach of the sociologists. But in the last analysis it is society itself which decides how much money and effort is to be ex-

pended on its social casualties, and by implication how much responsibility it is willing to assume in this field.

DAY AND NIGHT PSYCHIATRIC TREATMENT CENTERS: I DESCRIPTION, ORGANIZATION, AND FUNCTION¹

EUGENE KINDER, M.D., AND ROBERT S. DANIELS, M.D.²

Day and Night Centers facilitate the treatment of patients requiring more intensive and extensive treatment than can be provided in an outpatient setting and yet not needing full time hospitalization. Ordinarily the referring source has little choice in planning such treatment and must use full time hospitalization, which results in the patient giving up functioning in his family and society; and although relatively total separation is sometimes therapeutic, often it is not. Full time hospitals frequently place unnecessary restrictions on personal freedom; even the most flexible administration may require patients to adjust to the routine of the institution rather than having the institution adjust to the individual needs of the patient. The Day and Night Centers offer the advantage of encouraging the patient to continue in spheres of activity where he is relatively comfortable and competent, while simultaneously providing a therapeutic experience not unlike full time hospitalization. Participating in treatment while continuing to function in the external world reduces the artificiality of the hospital society and permits the patient to experience the interaction between his treatment and the external world in a more meaningful way. Continuing interaction with his family reduces concern about separation and fosters the family's integration into the treatment process.

The character of Day and Night Centers has varied widely, depending on the kind of patient accepted for treatment and the therapeutic goals. Some centers have been

limited to the care of a particular group of patients such as the aged(1) or chronic psychotics(2). Others have sought to provide a social club atmosphere where patients may derive emotional support from developing new interpersonal relationships (3). Still others have offered many of the services provided by the full time hospital (4-8).

The purposes of this paper are to describe the organization and operation of a Day and Night Center, and to define the types of patients who may be treated effectively. Case vignettes will demonstrate some of its specific advantages.

THE FACILITY AND THE PROGRAM

The Day and Night Centers of The University of Chicago Service of the Illinois State Psychiatric Institute,³ have a maximum capacity of 18 patients each and occupy the same physical facility. The unit, originally designed as a locked security ward, consists of 18 single rooms, a day-room area, and an occupational-therapy-recreation room.

The Day Center was organized to provide 8-hour treatment for ambulatory psychotics, elderly patients, unemployables, and "other patients not requiring full time hospitalization." The last, somewhat vague group, has expanded as experience has increased, and now these patients are similar to typical full time hospital patients. The therapy program is organized after the "total push"(9) pattern with emphasis on group activity therapy, group psychotherapy, psychodrama, patient government, and occupational, recreation and work therapies. The staff arrives on weekday mornings at 8:30 and after a short planning meeting meets the patients between 8:45 and 9:15 at a morning coffee hour. Thereafter, three times a week, small group psychotherapy is conducted by a

¹ Lester H. Rudy, M.D., Director, Jackson A. Smith, M.D., Clinical Director, and Miss Catherine Norris, R.N., Director of Nursing, Illinois State Psychiatric Institute, were helpful in organizing and operating the Day and Night Centers. C. Knight Aldrich, M.D., Professor of Psychiatry at the University of Chicago, was an active participant in the original planning of the Centers and his comments on this manuscript were of great value.

² Respectively, Asst. Clinical Professor of Psychiatry, Asst. Professor of Psychiatry, The University of Chicago, School of Medicine.

³ This hospital is an integral part of the Illinois Dept. of Mental Health. Adjacent to the Day and Night Center is a 30-bed full time hospital ward under the same administrative management.

third-year psychiatric resident. The whole group is divided in half so that each small group consists of 6 to 9 patients, a nurse and an aide.

On other mornings the hour is used for activity planning and ward government meetings, or a community-wide administrative meeting. When not involved in these meetings, patients engage in on-ward recreational, occupational and work therapies. Lunch is shared by patients and several staff members. The afternoon consists of recreational activities either in the gymnasium or out of the hospital. Once each week the entire group meets for psychodrama. Also in the afternoon patients are interviewed for vocational training and employment and may have work assignments in other areas of the hospital. At 4:00 P.M. the patients leave for home and the staff meets for an hour to discuss the events of that day and plan for the next day.

The Night Center provides a service to the remainder of the hospital. Patients hospitalized on other wards were transferred, when they became employable to the Night Center which is open 5 nights a week. The patient is expected to leave for work or home each morning and return each evening. Week-ends are spent either at home or in another suitable setting away from the hospital. Although initially planned solely to provide a transition phase between hospital and home and job, the Night Center soon began to accept direct admissions, thus expanding the potential therapeutic use of the unit. The night program includes group psychotherapy, social group work, patient government and activity therapy shared by all patients and staff. The night staff and patients arrive at 4:30 P.M. A family style dinner is served at 6:00 P.M. Three nights a week, between 7:00 and 8:00 P.M., a third-year resident leads group therapy which considers problems of community living and of leaving the hospital. On the other two evenings, a ward organization and planning meeting and a dynamically structural period of recreation are led by a social group worker. After 8:00 P.M. patients and staff gather informally for television, card playing, games, social parties and other activities. Patients retire between 10:30 P.M. and midnight. Breakfast is

served at 7:30 A.M. and the night patient returns to work or to his home.

The staff for each center consists of a staff psychiatrist (who supervises both centers), two female nurses, two male aides, a third-year psychiatric resident and a social worker. In the Night Center the nursing staff and aides are divided between two shifts. In the Day Center all are present simultaneously.

FUNCTIONS OF THE DAY CENTER

The Day Center has been of value in the following circumstances :

1. *As a definitive treatment center for many patients who do not require a full time hospital.* In such cases hospitalization may be damaging to the patient because it prevents him from using those psychological capacities which continue to function well. It also damages the community as it removes the patient from his usual social relationships and creates an unnecessary drain on community resources. The Day Center should be considered only if there are productive aspects in the patient's environment; if the family is willing to participate actively in treatment; and if the patient is not homicidal or suicidal.

Case 1. A 19-year-old single male was admitted complaining of paralyzing anxiety whenever he attempted to leave home. The patient and his mother reacted to admission with anxiety. He felt that he could not leave her and, at first, she insisted on remaining with her son. During the first 3 weeks, the patient gradually established relationships and became somewhat more comfortable. The staff then took the firm stand that the patient must come to the hospital alone. His new found capacity for independence was fostered and he subsequently planned to return to school and live separately. In the meantime intensive individual and group therapy with the mother enabled her to allow him to separate. On beginning school he asked to be transferred to the Night Center where he continued treatment.

2. *As a training center to reestablish work patterns and to facilitate job rehabilitation.* Chronic ambulatory psychotic patients often decompensate slowly over the course of several years. A patient who formerly worked regularly, gradually withdraws as his daily routine becomes too anxiety pro-

voking. Day Center treatment fosters the establishment of a regular routine of activity. The patient leaves home each morning for a place where definite but limited demands are made. He is encouraged to participate actively with other people in a variety of pursuits. He is frequently given responsibilities and ultimately work assignments in the remainder of the hospital. The creation of a job-like experience often provokes the patterns of conflict, characteristic of the pre-morbid performance in work relationships. The Day Center offers an opportunity for understanding and integration of these disruptive patterns. Vocational rehabilitation may then be started while the patient remains in the Day Center.

Case 2. A 28-year-old single man was admitted with a history of unemployment for 2 years. He lived at home with his mother and an older brother who supported the family. The older brother was planning to marry, and although he and two other siblings would continue to support the patient and his mother, the patient became anxious and hostile and complained that people were against him and persecuted him. For at least 10 years he had been somewhat withdrawn, apathetic and prone to spend a great deal of time alone daydreaming. The Day Center provided a structured situation in which the patient began to form interpersonal relationships. Although he remained isolated from most of the activities for a number of weeks, he eventually learned handicraft skills and several games. After 4 months he was given a job of delivering messages to other parts of the hospital, and he later was promoted to a mail sorting task. Still later he became actively involved in vocational rehabilitation and was transferred to the Night Center.

During the early part of hospitalization he continued to live with his mother, but later he moved to the home of a married sibling. Eventually he secured a small apartment. He was discharged after 11 months working regularly with an adequate independent living arrangement.

3. *As a treatment center for patients who, after a course of individual therapy, need additional treatment emphasizing interpersonal relationships and social factors.* In the course of individual outpatient treatment, patient and therapist occasionally recognize the need for another kind of

treatment experience providing new interpersonal relationships in a setting where these relationships are the focus of treatment. Such group treatment may serve to dilute a too intense transference relationship or may provide the patient with a ready-made opportunity to put increased self knowledge into operation. It may be necessary when the patient is too ill to create productive social situations for himself.

Case 3. A 29-year-old single woman, who had been seeing a psychiatrist on an outpatient basis for 3 years was admitted to the Day Center with symptoms of acute anxiety and depression. These symptoms had arisen when her therapist had decreased the frequency of appointments from twice weekly to once a week. Her therapist stated that she had been on a plateau for the past two years, focusing almost all her energy and attention on therapy. The Day Center staff and her outpatient therapist agreed that a period of day care might dilute the intensity of her relationship with her therapist and provide an opportunity to extend her interpersonal skills.

She remained for 10 weeks, becoming a leader in activity and psychotherapy. She commented, "I never quite understood what my therapist and I were talking about and how it applied to everyday life." The Day Center experience served as a practical demonstration of some of the factors she had previously dealt with only in an intellectual way in individual therapy.

4. *As a transition into the full time hospital when patient and family cannot tolerate immediate total separation.* Occasionally, during a diagnostic process, the evaluator believes that a severely ill patient should be in a full time hospital but recognizes that the patient and his family cannot accept the recommendation, because they are involved in a mutual symbiotic relationship. In a few instances these patients and families have been willing to accept treatment in the Day Center because they could reunite each evening. This compromise has been effective in itself in some instances; in others, it has led to full time hospitalization.

Case 4. A 19-year-old single man was admitted to the Day Center with a history of flatness of affect, looseness of associations, and delusions of persecution for at least 2 years.

He had been living with his mother who supported herself and the patient with a pension check and occasional day work. The severity and duration of the patient's illness suggested that full time hospitalization was indicated, but neither the patient nor his mother could accept that recommendation.

The patient began to form some tentative interpersonal relationships and to join in a few of the activities. In the meantime, his mother was involved in group and individual therapy with the social worker. Ultimately the patient and his mother were able to accept the need for full time hospitalization and he was transferred approximately 3 months after admission.

FUNCTIONS OF THE NIGHT CENTER

The Night Center has been helpful to patients in the following ways :

1. *As a temporary intermediate residence between full time hospitalization and total discharge.* Hospitalization is a gratifying experience for many seriously ill patients. The hospital and staff provide lodging, food, activity and secure interpersonal relationships while making relatively few demands on the patient. These gratifications are oftentimes difficult to relinquish at the time of discharge, and many patients experience an exacerbation of symptoms when preparation for discharge begins. Occasionally this separation reaction is so severe that it jeopardizes the results of the entire hospitalization. In such instances, the Night Center offers the patient an opportunity gradually to separate from the hospital and to reestablish family, social and work patterns.

Case 5. A 37-year-old married man with acute anxiety was admitted to the hospital with a history of an intensely dependent relationship with his wife, who had just delivered their first baby. During a four-month period of hospitalization, his symptoms abated and much of his dependency was transferred to the hospital. When discharge plans were initiated, he had an acute exacerbation of symptoms. When the therapist suggested than an intermediate step was indicated as a transition, his symptoms again abated. He secured work and was transferred to the Night Center for further treatment. He was extremely passive and demanding, making repeated requests for extra food and medication. Gradually, however, he became aware of his need to be the "baby." Ac-

tive interpretation of his conflict led to new awareness of his infantile dependent relationships with the nurses and his wife. His wife's participation in the relatives' group led to her increasing awareness of the patient's overwhelming dependency, his jealous rivalry with the new baby, and ways she might cope with these problems. He remained for 2 months and was discharged at his own request.

2. *As a temporary residence for the patient who has no family or other environmental supports.* The patient who is physically distant from family or friends or who has alienated them so that they will not offer help, faces a realistically difficult situation at the time of his discharge from the hospital. If in addition he has no job, a number of reality issues are present which may prevent him from giving up the protection and security the hospital provides. The Night Center permits a gradual solution of these problems.

Case 6. A 34-year-old psychotically depressed European immigrant was hospitalized 2 years after arrival in this country. After 4 months he was ready for discharge, but he had no external supports, lacking job, family and friends. The patient was a skilled tradesman and soon found productive employment. At that time he was transferred to the Night Center. When he became more comfortable on his job he began to look for a small apartment. Meanwhile, he used therapy to express his concerns about his approaching total separation from the hospital. He requested discharge after 2 months in the Night Hospital.

3. *As a temporary residence for the patient who is trying to separate from his family of origin.* Gradually increasing separation from the family of origin occasionally is a treatment goal, particularly when independence has been unduly delayed or the family situation is intolerable and unmodifiable. Even though the decision is jointly reached by patient, family and therapist, both patients and families find it difficult to relinquish one another. The Night Center combines treatment with the opportunity to try working and living apart from his family.

Case 7. A 27-year-old, white, single male was admitted to the full time hospital because of severe episodes of anxiety and re-

current ulcerative colitis. His family found it difficult to permit his hospitalization and for years had been alternating between overindulgence and rejection, thus keeping him tightly bound to them. After a long series of unsuccessful job and school experiences, the patient had become almost completely dependent on his family.

In the hospital he was supported in making the decision to separate from his family and he began to make plans involving little contact. He was transferred to the Night Center, and, during 6 months there, established himself at work and found a separate living arrangement. His relationships in the Night Center were similar in the beginning to his previous relationships with his parents. Clarification and interpretation of these were helpful in his ultimate separation from the hospital and from his family.

4. *As a treatment center where functioning at work or school may be maintained.* Some patients who require extensive treatment are still able to function adequately at work or school. When symptoms do not interfere with a particular aspect of social functioning, encouraging continued performance increases self-esteem and discourages regression. In the Night Center, the patient can continue to function at work or school while receiving psychologic treatment similar to that provided in the full time hospital.

Case 8. A 24-year-old, single, female professional school student was admitted with a long history of mild depression, recently intensified. She felt particularly lonely at night and often was unable to sleep. She walked for long distances, searching for something she could not define. She was tearful and frequently thought of suicide. In spite of her symptoms, she continued performing adequately in school and was well thought of by her instructors and classmates. After she was admitted to the Night Center, her school performance continued at a high level, even though her symptoms persisted during the first 2 months of hospitalization. In the course of treatment she became aware that her crying and depression were related to a delayed grief reaction to her mother's death 7 years before. She was discharged to outpatient care after 4 months.

PATIENT, STAFF, AND FAMILY RELATIONSHIPS TO THE CENTERS

The role of "patient" is defined by social

tradition and experiences. The public's expectation of a "psychiatric patient" resembles that of a "medical patient" in that it involves helpless dependency in a hospital environment. Psychiatric hospitalization also often includes extended separation from family and community. The staff of psychiatric hospitals are conceived as uniformed, authoritarian figures who provide total care and control of the patient. The public, staff members and patients foster these images and insist that they view one another in these stereotyped terms. These traditional roles may be anxiety reducing to all concerned, but they interfere with meaningful therapeutic interaction.

The Day and Night Centers are organized to minimize these expectations and to emphasize responsibility, collaboration, freedom and open communication. The modification of roles and increased closeness of interpersonal relationships are major potential advantages of this type of treatment. However, they may create difficulties for staff and patients, particularly in the early phases of their relationship with the Centers. With the assistance of competent and sensitive leadership, the members of this unit can be helped to integrate these potentially anxiety producing factors into effective treatment. These advantages and difficulties are extensively considered in a recent communication by Werner, Holmes, and Lefley,⁴ arising out of their experience as nursing staff members in this unit.

The continuing interaction between patient and family in the Day and Night Centers promotes a feeling of increased importance for the family. The traditional hospital environment often separates patient and family for an extended period and reduces the family's anxiety to such an extent that their participation in treatment is limited. As a result of the emphasis on social organization in these centers, families are often dealt with in a group setting. They

⁴ For a comprehensive view of the functioning of nursing staff in this unit see Werner, Holmes, and Lefley "Day and Night Psychiatric Treatment Centers: II—Opportunities for Creative Nursing" presented at the second annual Illinois State Psychiatric Nursing Conference held at the Illinois State Psychiatric Institute on Sept. 7-8, 1961. Mimeographed copies are available on request.

have the opportunity to share and compare experiences; to overcome feelings of uniqueness and isolation; to derive support from one another; and to begin to understand their interactions with their patient, with the rest of their family and in the group. Family group meetings do not exclude the possibility of individual contacts or of family therapy. The decision to use group or individual techniques is based on the dynamic understanding of the patient and his family structure.

The establishment of a new and different treatment facility inevitably leads to administrative problems, particularly when the facility requires a departure from traditional methods of operation. The Day and Night Centers required reorganization of existing physical facilities and an unusual degree of administrative flexibility. In addition, these units are dependent on intramural and community referrals. As a re-

sult, relationships with the remainder of the hospital and with the community assume special importance.

THE TREATMENT OF DEPRESSION IN HOSPITALIZED PATIENTS BEFORE AND SINCE THE INTRODUCTION OF ANTIDEPRESSANT DRUGS¹

WILLIAM J. TURNER M.D., FRANCIS J. O'NEILL, M.D., AND
SIDNEY MERLIS, M.D.²

In 1957 monoamine oxidase inhibitors were proposed as therapeutic agents in treatment of depression(1). In the same year Kuhn reported on his favorable experience with imipramine(2). It has seemed worthwhile to determine to what extent these drugs have found acceptance and have proven themselves in the field of the admission service of a large state hospital. To that end we have examined the records of the years 1955 and 1960 at Central Islip State Hospital, and have consulted with the various staff members. It is on their work, their views and their results that this paper is based; for any misunderstandings we may have of their views, we offer apologies.

Our interest in this matter arose in 1959, when we tried to assemble a group of patients for trials of antidepressant medications. On the basis of published statistics, and from the experiences of past years, we expected to find between 300 and 400 depressed patients. To our astonishment, in this hospital of nearly 10,000 resident patients, we found only 73 depressed under the age of 75, and less than 50 suitable for drug trial(3). For many years there has been a steady decline in the rate of first admissions of depressed patients into New York state hospitals(4), *e.g.*, the rates for manic-depressive and involutional depression fell from 17.1% of total admissions in 1920, to 11.6% in 1935, and 9.1% in 1950. This is a general phenomenon in the United States, commented upon by many writers; against this our colleagues in Spain, Switzerland and Scotland report no such trend in their experience.

Our first consideration then was to try to account for the drop noted and to ask: Are these patients now being hospitalized representative members of the population hos-

pitalized before the advent of the antidepressants? We immediately noted that there appears to be great fluctuation in the yearly admission rate: there were 88 manic-depressive psychoses brought to the female admission service in 1920, 106 in 1930, 42 in 1940, 22 in 1950 and 82 in 1960. This is a real fluctuation, as the same psychiatrist was in charge throughout the whole 40-year period, and those who knew her were impressed by her thoroughness and consistency. While we can not go into the social and administrative reasons for these variations, we must recognize that statistics cannot be used in this population without most careful attention to myriad details. A second question, much debated, was whether the increased EST, drugs, and psychotherapy in extramural practice reduce the number of patients requiring hospital care, whether this alters the clinical picture of those who are admitted, and whether this biases the type of depression admitted in favor of those not benefited by the therapies available. As to this we have some affirmative evidence, but it turns out other than expected. We had 202 patients admitted in 1955 with one or another of the following diagnoses: senile psychosis with depression; involutional melancholia; manic-depressive (depressed or other); alcoholic psychosis with depression; reactive depression, and a small scattering of other diagnoses with depression as a major manifestation. In 1960 we admitted 248 such patients. A breakdown by age, sex and diagnosis revealed that there were fewer of the older patients with manic-depressive and involutional disorders in 1960, more than made up by the increase in the younger persons with more psychoneurotic and reactive depressions. For this we have a ready explanation: publicity of improved conditions at the Central Islip State Hospital has resulted in a rise of voluntary admissions from 3% in 1955 to 40% in 1960. We are now admitting

¹ Read at the 118th annual meeting of The American Psychiatric Association, Toronto, Canada, May 7-11, 1962.

² Research Division and Clinical Facilities, Central Islip State Hospital, Central Islip, N. Y.

many patients who would never have come in under certification procedures. As to whether we have fewer of the older psychotic reactions because of improved extramural therapy we have no data at all.

We have also raised the question whether cultural changes in the past 50 years, within the area from which our patients come, have shifted the clinical pattern of illness. Depression is intimately connected with inability to express one's feelings in words. Certainly we have become a more outspoken people in the past 50 years, and we no longer hear, "Children should be seen, not heard." If normal grief and sadness are manifestations of submission under defeat suffered in a conflict with reality (loss of loved one, personal injury and disfigurement), and if melancholia and depression are manifestations of submission under defeat in a conflict with "superego" (not living up to conscience, inability to live according to desired mode out of respect for a family), then the frequency of and the psychologically permissible operations under defeat must change with social conditions. It is a commonplace in institutional experience that a large proportion of patients diagnosed manic-depressive in early life exhibit increasing thought disorder and eventually are called schizophrenic. We do not wish to enter this field of polemic, but we have wondered whether further and repeated hopeless defeats following upon a resurgence of hope may be a condition for the development of the schizophrenic picture. If so, then partially successful extramural therapy could result in first admission of patients as schizophrenics who had come originally for treatment as depressive reactions.

This last point raised one final set of questions which we must briefly consider as bearing on the diagnosis of depression and evaluation of the treatment of those so diagnosed. The various clinical aspects of defeat, despair, hopelessness, discouragement, unhappiness, and so on are so manifold that they may be discerned at one or another level of observation and in every imaginable context. Ayd(5) has written extensively along these lines, but the psychoanalytic literature is replete with the evidence that in one way or another de-

pression, of whatever degree, is ubiquitous. In order to limit ourselves to a study which we could carry out we have, with knowledge beforehand, defined as examples only those patients diagnosed by our staff as suffering one of the disorders named earlier.

It is to the treatment of these patients we now direct attention. These treatments reflect the philosophy of the physician in charge of the service, modified by the combined experience and attitudes of the various staff members, including the higher administrative officials. In a very large hospital the weight of responsibility for large numbers of patients, as well as to the community, demands a degree of reluctance in the adoption of new procedures. We cannot follow hot after every view-halloo. A new procedure is tried tentatively, once, twice, more times; if it looks favorable, trial is extended and intensified. It is in this phase that we seem to find ourselves now at Central Islip with respect to the antidepressants, and it is in this context that we present our data.

Where treatments are given according to a wide variety of rules it is most difficult for a follow-up to assign outcome to one or another course of action. As we reviewed the patients' folders, and discussed matters with the staff, we were often puzzled and uncertain as to how to categorize a treatment schedule. Beyond this, of course, we had not a single clue as to the meaning of any treatment to the individual patient, nor did we have any clue as to the social relations which might have been related to illness or to recovery. This serious flaw is, of course, found in nearly all, if not in every drug report we have ever seen. We cannot condone it; we must merely report it. We have tried to use our best judgment in setting down treatments as if they were singular and mutually exclusive.

First, the antidepressants must compete in effectiveness with no treatment, with EST, with phenothiazines, with other drugs, and with psychotherapy. As to the last-named, this has been of such irregular nature, never fully intensive, that we must consider it as a random factor. The usual stimulants and sedative-hypnotic drugs have been used as occasion suggests, not as the basis of therapeutic regimens; our ex-

perience, like that of the rest of the world, generally is that they are symptomatically useful and even valuable, but do not influence the course of depression in a hospitalized patient.

TABLE 1
Duration in Hospital by Diagnosis, all Therapies

		0-12 MONTHS	12-24+ MONTHS	DIED	REMAIN IN HOSP.
Senile psych.	1955	: 5	: 8	: 11	: 1
	1960	: 7	: 1	: 6	: 0

	1960	: 29	: 7	: 0	: 10
M-D, dep.	1960	: 34	: 1	: 1	: 6
	1955	: 43	: 9	: 3	: 1
M-D, other	1960	: 35	: 9	: 2	: 16
	1955	: 25	: 3	: 1	: 2
Other diag.	1960	: 70	: 4	: 1	: 9
	1955	: 34	: 10	: 5	: 2

In Table 1 is presented the duration in hospital by diagnosis of the patients admitted with depressions in 1955 and 1960. On the one hand we note that there were a number of deaths in all diagnostic groups and, as would be expected, more in the seniles. These deaths do not reflect suicides, of which there was one, but rather intercurrent or concurrent physical diseases, chiefly in the older patients. On the other hand, we note how few patients remain in the hospital more than 12 months, and how very few more than 24 months. Of the 202 admitted in 1955, after 24 months there were only 13 in the hospital; of 248 admitted in 1960 only 41 (and these were leaving at the rate of 3-6 a month as our study closed). It is also noted that the discharge rate was high for all diagnostic categories.

In our 1961 study we were struck by the number of patients who improved and were discharged with no special therapy. In this present work we were struck equally by the evidence that a great percentage of the patients showed marked improvement almost as soon as they were admitted and before any special therapy. This seems to

be so particularly for those who attempted suicide; by diagnostic group the reactive depressions seem to respond well to simple hospitalization. In 1955, 50 patients had no special treatment, yet 38 of them were discharged alive; 10 others, too ill for treatment of depression, died. In 1960, of 36 patients well enough to receive treatment but who did not have any special therapy, 21 were discharged alive. It is of interest that in both years there were significant numbers of involutional melancholias and manic-depressive psychoses among these. The rate of "spontaneous recovery" in these patients cannot be ignored in evaluating therapeutic regimens.

We must further remark on the occurrence of spontaneous remission or of long-continued resistance to treatment which seems to occur in clusters. It strikes us that certain patients on the ward at one time or another, or some group of social forces in the environment, play great roles in determining the occurrence of these clusters. This is another of the many complications in evaluating drug therapy.

The number of patients who received EST was not greatly in excess of those who had no special therapy: 61 in 1955; 39 in 1960. Their discharge rates were much higher, however: 95% in 1955; 79% in 1960. We cannot attach importance to minor variations in recovery rates by EST among the various diagnostic groups. We note, however, that the increasing rate of admission of younger patients with reactive depressions, depressions associated with alcoholism, and neurotic depressions has largely been of voluntary nature. These patients rarely require or give permission for EST, a fact reflected in the drop in the EST rate between 1955 and 1960. This drop is not due to the increased use of new drugs. On the other hand, much of the increased use of new drugs is due to factors which produced this drop.

Judgment is most difficult: in the use of drugs some patients had a few ESTs, with some improvement before the drug was administered; some had EST with partial relief of depression but with residual or increased anxiety which was treated by drug; in some the drug was used intermittently, or for a time before improvement

set in; in still others, the percentage of which we cannot say, improvement set in shortly after the drug administration began. In those patients who had considerable thought disorder, whom we might call schizo-affective, the phenothiazines were undoubtedly useful. These agents, too, were particularly employed when agitation and anxiety predominated over depressive signs. In Table 2 it will be seen that the use of phenothiazines did not change much between 1955 and 1960.

TABLE 2
Prognosis With Use of Phenothiazines and Antidepressants, by Duration and Outcome

		0-12 MONTHS	12-24+ MONTHS	DIED	REMAIN IN HOSP.
Phenothiazines	1955	: 53	: 8	: 12	: 15
	1960	: 60	: 6	: 2	: 10
MAO inhibitors and Tofranil	1960	: 32	: 0	: 0	: 6

With respect to the antidepressants it is of interest that experienced clinicians chose only 38 of 248 depressed patients admitted in 1960 to be treated by these newer agents. Thirty patients of the 1960 group were treated with MAO inhibitors. Of these, 27 were discharged within the observation period. Eleven were psychoneurotic depressions, 8 were manic-depressives and 8 were involutional melancholias. The brief hospital stay of the involutional melancholic patient is truly remarkable: 5 were discharged in less than 3 months. Those with long memories will recall the 3- to 5-year stay of such patients prior to 1940.

Of the 8 patients treated by imipramine in the 1960 group, 5 were discharged, with a hospital stay of more than 3 months each. Consultation with our staff revealed that there was, in 1960, some hesitation in adoption of imipramine and amyltriptyline, particularly since such excellent results were to be had by other therapies. In 1961 the use of imipramine increased and is apparently displacing the other drugs. However, it is still too early to use our data to discuss this point.

There is no doubt that there is a great

change occurring in the nature and degree of depressions found in New York state mental hospitals. In our search for depressed patients we could not find one with the severe degree of depression so often described and pictured in textbooks of 20 and more years ago. The descriptions by Kraepelin in his *Manic Depressive Insanity and Paranoia* (6) have no present-day examples. It used to be that the majority of depressed patients were in maximum security wards and precautions against suicide were among the most important preoccupations of the ward personnel. Not now! The depressed patients are on admission services, frequently on open wards and many have honor cards. In the years 1960 and 1961 there were only 5 seriously suicidal patients on the admission service. Three were schizophrenic and 2 were alcoholic.

The value of EST has been so great that there has been a reluctance to turn to drug therapies. Nonetheless, the antidepressants are becoming accepted and used in selected cases. As their range of usefulness becomes known with more experience, we may expect even better results. Beyond this, the atmosphere of hope and emotional support offered today by many modern psychiatric hospital admission services is of enormous therapeutic value.

CONCLUSIONS

A study of the rates of admission, therapy and outcome of depressed patients at Central Islip State Hospital for the two years 1955 and 1960 is reported. A drop in the admission rate for the more severely psychotic depressions has been balanced by a rise in admission rate of reactive and neurotic depressions. The high value of EST in the severe depressions is again revealed by our data. There is evidence for high value of phenothiazines in the agitated and in the neurotic depressions. There has been surprisingly little use of the MAO inhibitors and of imipramine, despite the reported value of these drugs. The hopeful, protective and supportive attitude of admission services is in itself highly therapeutic. All in all, the present prognosis for a depressed patient admitted to hospital is highly favorable and constantly improving.

DISCUSSION

ALFRED PAUL BAY, M.D. (Topeka, Kansas).—A century or so ago Griesinger remarked that natural cataclysms, war or civil disruption had no effect on the incidence of mental illness. Although no substantial evidence has refuted the general truth of his statement, yet there are facts such as those offered in this paper which seem to be at variance with it. The authors' experience seems to indicate that something has happened to change the kinds of depressed patients who seek their help, and comparable data on patient admissions to the Topeka State Hospital confirm their findings. Over the same 10-year period, the total admissions to Topeka State Hospital increased from 200 a year in 1950, to almost 1,000 a year in 1960. At the same time the percentage of admissions suffering from depressions rose slightly from 7% in 1950, to 9% in 1960.

However, the percentage of psychotic depressions fell from 6% to 3%, while the percentage of reactive depressions rose from 0.6% to 6.1% in the same period. In 1960, 64% of depressions admitted were called "reactive depression."

What are the possible explanations of the decrease in severe psychotic depressions seeking hospital admission? It could be an actual decrease in the incidence of such depressions—contrary to Griesinger's hypothesis. It could be that the use of other treatment facilities, such as the family physician, the general hospital, or the outpatient clinic, is serving this group of potential clients. Or, as the authors have suggested, the cultural change which encourages the substitution of expression for depression may be the responsible agent. Of these explanations, I would question very much that these cases are now being cared for by men in general practice. Actually, a well developed depression is one of the few things

which most general practitioners are reluctant to play with, and we look upon a severe depression as one of the few valid emergency situations because of the ever present threat of self-destruction.

Certainly, quite different etiological factors are at work in the several varieties of depression which our nomenclature differentiates, and it is a curious fact that in depressions associated with organic conditions, such as senility, arteriosclerosis, and metabolic diseases—about which we profess to know the least—there is the greatest reduction in admissions. On the other hand, in the psychoneuroses, where the psychological determinants (about which we feel we know so much) are predominantly influential, we have an uncomfortably large increase in incidence.

In another aspect our experience differs from that of the authors, that is, the choice of treatment. At Topeka State Hospital, where psychodynamics is the preoccupation of the staff, EST was abandoned with feelings of relief as the various chemical agents became available. Our treatment of choice has been (since 1950) and still is consistent attitude and milieu; a compulsive, demanding environment for anaclitic depressions, or an authoritarian, ego supportive and purposefully busy program for neurotic depressions. The advent of new drugs has in our hospital had the effect of removing almost the last excuse for giving EST, a result which I personally regret because I believe it can dramatically shorten a protracted and obstinate course in some of these patients.

Dr. Merlis' paper does not settle as many questions as it raises. Why, for instance, do we have the steady increase in numbers of reactive depressions: is it because of the economic good-times which the country enjoys? We Americans are pretty sleek and fat. To thinking animals, such as mankind, the lack of clear cues to a course of action is in itself a stressful condition, and may produce anxiety and depression. Stressful times and stressful situations have their value insofar as they simplify decision making and choice of action.

Dr. Merlis points to the good results obtained with several kinds of therapy; even no therapy (aside from the supportive effect of being hospitalized) often brings about good clinical results. This makes one speculate on what is the objective of treatment—is it symptomatic relief, with externalization of aggression, or substitution of another defense mechanism? Is it social restoration of the patient? Or is it a reshaping of the patient's personality in such a way as to make him invulnerable to future stresses? In the public mental hospital,

where the more limited goal is more likely to be the case, what effect does this choice of goal have on the choice of treatment?

One might even ask why look for better treatments for depression than those we now have? A recovery rate of 95% (as obtained in some series) is almost comparable to that for chicken pox or measles. Of course—the obvious answer is that as long as we can provide greater hope of recovery for even one more patient than yesterday offered, we will continue to look for better treatments. As long as we can shorten the length of hospital stay by even one day we will try to do so; but with

several potent therapeutic agents at our disposal, it does not necessarily make the choice of treatment easier. It merely means that some much more critical studies of the different treatments for the various types of depression are badly needed.

It would be interesting if two or three hospitals could each commit themselves to try a different treatment regime for some specific diagnostic groups for a year, and then exchange methods for the year following. Such a co-operative study would help to reduce the effect of staff prejudices in reports of therapeutic results.

IMIPRAMINE IN DEPRESSION : A CONTROLLED STUDY

NORMAN ROULET, M.D., ROBERT R. ALVAREZ, Ph.D.,
J. PATRICK DUFFY, M.D., L. DOUGLAS LENKOSKI, M.D.,
AND T. GEORGE BIDDER, M.D.¹

Imipramine (Tofrānil)² was first described as an antidepressant drug in 1957 (1). Since that time, numerous reports have appeared on its use. These have, on the whole, ascribed significant effectiveness to the drug in the management of depression, but only a few (2-5) have stemmed from controlled clinical trials. Depression is influenced by many things that are obscure at the present state of our knowledge. Therefore, we believe that an evaluation of any therapy for depression should be carefully controlled. As a means of achieving such control, we chose a double blind technique.

This study was conducted at Hanna Pavilion, a 75-bed psychiatric division of the University Hospitals of Cleveland. The Hanna Pavilion has a large outpatient division where many depressed patients are treated; only the more severely ill, in general, are admitted, and only these were included in the study. Their diagnoses are shown in Table 1.

TABLE 1
Diagnoses of Imipramine- and Placebo-Treated
Depressive Patients

	DRUG GROUP	PLACEBO GROUP
Depressive reaction	17 (89%)	16 (76%)
Psychotic depression	2 (11%)	4 (19%)
Manic depressive reaction, depressed type	0 (0%)	1 (5%)

We required the presence of delusions for the diagnosis of psychotic depressive reaction and that of involutional psychotic reaction, thereby considering some otherwise "deep" depressions to be in the neurotic category, i.e., depressive reaction.

Every staff (non-private) patient admitted with one of these 3 diagnoses was

assumed to be on the study. (We also would have included patients with a diagnosis of involutional psychotic reaction, but none happened to be admitted during the period of the study.) Provision was made, however, to exclude or drop patients from the study should participation in it present a danger or hardship. Two patients were thus excluded and one was dropped.

After a patient had entered the study, he was evaluated by a senior psychiatrist and was in addition given a battery of psychological tests. Tests were chosen that yield objectively scored estimates of a variety of emotional, language, motor, and perceptual functions and included the Minnesota Multiphasic Personality Inventory (MMPI), the Trail Making Test, Wechsler's Digit Span and Digit Symbol tests, and a finger-tapping test. Serum bilirubin, serum transaminase, hematocrit, and white blood count and differential were determined. When these baseline studies were completed, the patient was assigned to either the drug or placebo group on the basis of a scheme of randomized numbers.

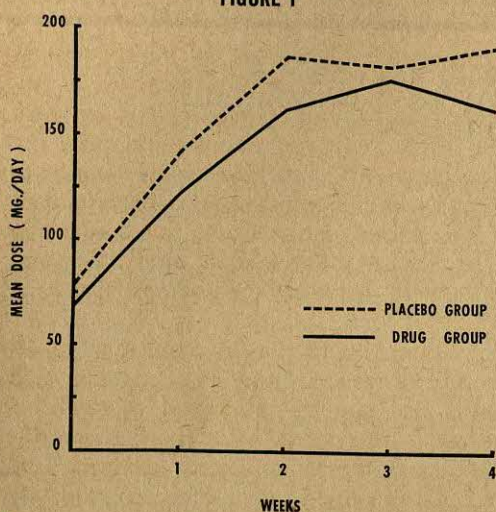

In the interest of achieving a natural clinical situation, the patient's physician was given free choice regarding dosage of the tablets, amount and form of psychotherapy, and selection of such ancillary measures as occupational therapy. He was urged, however, to acquaint himself with the recommendations of the manufacturer and investigators for the use of the drug. The only restrictions imposed was against the use of additional "psychotropic" drugs other than barbiturates during the period of the trial. As we were attempting to isolate a pharmacologic effect, we thought it important to minimize such a variable as the actions of other drugs.

The mean doses of the drug or equivalent of the placebo are shown in Figure 1. The differences between the mean doses in the 2 groups are not significant ($p=.20$). These doses are in the range that the manufacturer and various investigators report as

¹ University Hospitals of Cleveland and the Dept. of Psychiatry, Western Reserve University School of Medicine.

² Tofrānil tablets and matching placebos were generously supplied by Geigy Pharmaceuticals, Yonkers, New York.

FIGURE 1

therapeutic(6-8). Although such things are not easily quantitated, we think that the 2 groups may be considered also to have received comparable management in the way of psychotherapy, adjuvant measures, and exposure to various features of the hospital milieu.

The length of the trial for each patient was 4 weeks, during which time the blood studies noted were repeated weekly, but the patient was not otherwise formally evaluated. We believe a 4-week trial was sufficient, in that reports suggest that if imipramine is to be effective it will most likely be so during this period of time. Also, practically speaking, any non-psychotherapeutic antidepressant measure that requires more time than this is of limited usefulness, considering the usual prompt efficacy of ECT in the type of patient we were studying. A few patients were enough improved before the end of the 4 weeks to be discharged early and to receive their final evaluations as outpatients. Otherwise, at the conclusion of a trial a patient was again evaluated in the same manner as he had been initially. Following this evaluation, the patient's regular physician chose what additional treatment, if any, he felt was needed for the patient.

As an aid to objective evaluation, we devised the rating scale shown in Table 2.

TABLE 2
Clinical Rating Scale for Evaluation of Depressed Patients

	0	1 (MILD)	2 (MODERATE)	3 (SEVERE)	WEIGHTING COEFFICIENTS
1. Food intake and weight loss	Normal	Anorexia without weight loss.	Weight loss less than 10% of body weight.	Weight loss more than 10% of body weight.	3
2. Insomnia (night sleep)	7/8 of normal amount or more	Normal amt. of sleep on a single hypnotic dose of sedation.	Normal amt. of sleep obtained with 2 or 3 times the hypnotic dose of sedation.	Sleepless. (Normal amt. of sleep not obtained on 3 times hypnotic dose of sedation.)	3
3. Loss of self-esteem	None	Feeling not worth as much as before.	Feelings of worthlessness.	Delusions of guilt.	2
4. Functional somatic complaints	None	Present but not complaining spontaneously.	Complains spontaneously.	Somatic delusions.	1
5. Suicidal content of thought	Not present	Wishes himself dead.	Suicidal thought without plan.	Definite plan to commit suicide.	3
6. Anxiety	Not present	Subjectively observed only.	Anxiety objectively observable but not incapacitating.	Incapacitating. (Pacing, hand wringing, patient unable to sit still.)	2
7. Stream of talk	Normal	Feels retarded but not apparent to examiner.	Present but can talk in sentences.	Unable to talk in sentences.	2
8. Level of activity	Normal	Normally active but does not want to be.	Less active than usual.	Inactive.	2

The items in the scale were chosen and their criteria defined by the authors of this paper. The items were then weighted according to a system of coefficients derived from the polled opinions of 3 psychiatrists. The purpose of weighting the items was better to estimate their relative practical importance in the assessment of depression. To increase precision the same psychiatrist, using this rating scale, evaluated all the patients in the study.

RESULTS

Weighted scores for each patient were obtained from the rating scale by multiplying the numerical judgment for each item by the weighting coefficient for the item, adding the products thus obtained, and dividing by the sum of the weighting coefficients. The higher the score, then, the greater the degree of depression indicated; the greater the difference between the initial and final scores, the greater degree of improvement shown during the period of the trial. The scores were then analyzed in two ways: by comparison of the means for the two groups, and by comparison of patients paired by severity of depression indicated in the initial ratings. The results are shown in Table 3.

TABLE 3
Clinical Rating Scale Results for Imipramine- and
Placebo-Treated Patients Before and After a
Four-Week Medication Period

RATING SCALE TOTAL SCORE	DRUG GROUP	PLACEBO GROUP
A. Comparison of Means		
Before treatment		
N	19	21
Mean	1.39	1.41
SD	0.32	0.31

N	18	21
Mean	0.68	0.87
SD	0.55	0.71
Difference between before and after treatment scores		
N	18	21
Mean	0.71	0.54
SD	0.45	0.66
t ratio		0.98
p		.40
B. Comparison of Matched Pairs:		
p=.48		

On the basis of the clinical rating scale, the patients in the drug and placebo groups were equally depressed at the beginning of the trial. Both groups of patients improved during the course of the trial, with the drug group improving more than the placebo group; but this greater improvement was not significant ($p=.40$). Analysis of the paired patients also failed to show a significant difference in amount of improvement between the two groups ($p=.48$).

A common practice in reporting the effects of drugs is to describe changes in such terms as "slightly improved," "good response," "recovered." We think these distinctions rather vague and arbitrary and are not inclined, therefore, to indicate levels of improvement on the basis of our clinical rating scale, even though our results are quantitative. We believe, however, that certain pragmatic tests can be used to establish such levels. For example, at the Hanna Pavilion a depressed patient is usually not discharged until he has improved to a point at which little, if any, depression remains. The fact of a patient's discharge thus establishes a certain practical level of improvement. Some patients in the study were discharged prior to, or at the conclusion of the 4-week period, thereby indicating that they had reached this level of improvement within the trial period. The other patients remained in the hospital for various periods of time and received further treatment. Those patients with the most refractory depressions were generally given ECT. We think that useful indices of imipramine's efficacy are provided by comparisons of the drug and control group as regard discharge during or at the conclusion of the trial, length of hospitalization beyond the 4-week period, and ultimate use of ECT. Table 4 summarizes these data.

Here again it can be seen that we found no statistically significant difference between the drug and control groups.

A claim has been made that imipramine reduces the number of ECTs needed should the drug itself not effect sufficient improvement to obviate their use (9, 10). Patients in the drug group who eventually received ECT required a mean of 6.4 treatments, those in the placebo group a mean of 8.0

TABLE 4

	DRUG GROUP	PLACEBO GROUP
Number of patients discharged during or at the conclusion of the trial	4 (21%)	5 (24%)
Mean number of days of hospitalization beyond period of trial	27	28
Patients eventually receiving ECT before discharge	5 (26%)	7 (33%)
	(p=.89)	

treatments. The difference is not significant ($p=.44$) and our data thus fail to support the claim.

Analysis of the MMPI showed improvement in both groups, except that the placebo patients scored slightly worse on scale *Hy*. The mean standard score for the 9 MMPI clinical scales yielded a significant difference ($p<.025$) in favor of the drug group as did 5 of the individual scales (*Pt*, $p<.01$; *Hs*, *D*, and *Sc*, $p<.05$). Of the tests of language, motor, and perceptual functions, only Digit Span yielded a significant difference ($p<.001$). Whereas the placebo patients improved their digit span, the drug patients showed a poorer mean performance after treatment. The memory component of Digit Span is considered to be minimal, and it is assumed that the test essentially measures attention(11, 12). Imipramine has a well established central nervous system depressant action(13). The dysfunction in this test shown by the imipramine patients may therefore reflect a decreased sensitivity to environmental stimulation. Such a drug effect might thus also have served to reduce deviant MMPI responses, particularly on scales heavily loaded with items pertaining to anxiety and physical complaints. This seems to have been shown by our patients, in that MMPI items relevant to feelings of anxiety and physical malfunction are most heavily represented in those scales that differentiated the drug and placebo groups. The scale that differentiated most strongly was the *Pt*, a measure highly correlated with anxiety. The *D* scale, while showing results favoring the drug group, attained the lowest *t* value of the scales that proved significant. This scale, however, is known to consist of heterogenous

factors and corresponds only partly to the clinical definition of depression(14). In our rating scale we chose to assign weighting coefficients of relatively low value to "functional somatic complaints" and to "anxiety," which may explain part of the difference in results from the rating scale and MMPI. Data from the psychological tests, then, suggest that imipramine has a measurable effect, but not one specific to depression.

No detailed study was made of side-effects, but certain qualitative impressions were obtained. There were no serious untoward reactions to the drug. One patient receiving it developed a rash, but this cleared with slight reduction in dose. Two patients in the placebo group had syncopal episodes that were thought at the time to be "drug effect." Such symptoms as dry mouth, excessive perspiration, and dizziness occurred in some patients but were on the whole mild—and were not restricted to the drug group. The weekly laboratory studies showed no abnormalities in any of the patients.

A problem in the performance of a double blind study can arise from the curiosity of personnel as to the identity of the medication being dispensed and their attempts to distinguish drug from placebo. The physicians who participated in the study were asked which type of medication they had thought, during the trial, each of their patients was receiving. Only 57% of their estimates were correct: 23% mistook drug for placebo and 20% placebo for drug.

DISCUSSION

In this study, imipramine was found not to be superior to the placebo in the treatment of depressive disorders in our patients in our hospital setting. There were significant differences in several of the psychological tests favoring the drug and appearing as evidence that imipramine has some measurable psychopharmacologic actions. These actions, however, did not seem to be of practical benefit to our patients, in that every criterion of clinical improvement we applied failed to show a significant difference between the drug and placebo groups.

This is not to say that patients who received the drug failed to improve. They did improve as a group, but not significantly

more than did the placebo group. There were several individual patients who received the drug and showed very marked improvement, but this was also true of several of the patients who received the placebo. Without the use of controls, our clinical impression of the drug would have been speciously more favorable.

Reports on the use of psychiatric drugs have often shown striking differences in the effectiveness that they attribute to a given drug. Such diverse findings may be due to lack of controls, to improper selection of patients, to differing diagnostic formulations among investigators, to the difficulties in assessing change objectively, to the inclusion of drugs other than the one supposedly being tested, or to lack of statistical analysis. At times, however, none of these seem clearly at fault, and the variation in therapeutic results defies explanation. It was not within the scope of this study to investigate such a basic problem in drug evaluation. Its existence must always be kept in mind, however, if drugs are to be used rationally in psychiatry and if the total therapeutic process is eventually to be understood.

SUMMARY

The antidepressant drug imipramine was evaluated by means of a double blind study. Therapeutic results were assessed on the basis of a rating scale, psychological tests, and clinical course. Differences favoring the drug were found in some of the psychological tests, but in no clinical area were

there significant differences between drug and placebo.

We wish to thank Dr. Glenn Bartsch and Dr. George Badger for their help with the design of the study and with the statistical analysis of its results.

PSYCHIATRIC REACTION PATTERNS TO IMIPRAMINE¹

DONALD F. KLEIN, M.D.,² AND MAX FINK, M.D.³

Clinical psychiatric experience demonstrates a wide range of variation in behavioral responses to physiological therapies. Present techniques of evaluating therapies by global improvement scores, imprecise diagnostic classification, and target symptoms abstracted from their context were felt to be methodologically inadequate. Following our experience in describing the behavioral reaction patterns to convulsive (4) and phenothiazine (6) therapies, a similar analysis of the data derived from imipramine (Tofranil) therapy was undertaken.

In this report various patterns of behavioral response to imipramine are described; and the relationship to such factors as age, sex, pretreatment behavioral pattern, hospital diagnosis, and hospital discharge evaluation are assessed.

METHOD

Hillside Hospital is a 196-bed, open ward, voluntary psychiatric facility for the treatment of patients with early and acute mental disorders whose stay is independent of their ability to pay. All patients are seen in individual psychotherapy, with the expectation that psychotherapy should be given a trial prior to other measures. Somatic therapies are employed by joint decision of the resident therapist and supervising psychiatrist, with the management of medication restricted to the research staff.

Before starting medication each patient is interviewed by a research psychiatrist. During drug therapy the patient's response is assessed in weekly interviews with both the patient and ward personnel, reviewing changes in mental status and hospital ad-

justment. In biweekly conferences with the psychiatric resident and his supervisor the patient's progress in psychotherapy, affective and symptomatic state, utilization of hospital facilities, and social and familial relationships are discussed.

When it was evident that the standard diagnostic nomenclature was of little use in categorizing behavioral reactions to drugs, and that psychodynamic formulations lacked predictive clarity, it was decided to derive a descriptive behavioral typology for each agent studied. The detailed longitudinal research records were reviewed and a summary statement concerning the patient's behavioral reaction during treatment was made. The patients were categorized on the basis of changes in symptoms, affect, patterns of communication and participation in psychotherapy and social activity. In each category the drug reaction was the determining feature. While no attention was paid at this point to the patient's pretreatment behavioral patterns, except as relevant to the perceived changes, inspection of these groups showed that not only did the patients share similar behavioral changes with drug therapy, but that they also showed similar behavioral pretreatment characteristics.

For certain patients no discernible change in behavior was observed. It was possible to characterize these subjects by their pretreatment behavioral patterns alone, and these patterns did not occur among those groups showing an imipramine effect.

Treatment was begun orally at 75 mg. daily and usually increased each week in 75 mg. steps, to a modal maximum of 300 mg./day in 80% of the patients.

Between October 1958 and July 1961, 215 patients received imipramine. During the early use of the drug it had not been firmly established that an adequate trial of medication required at least three to four weeks. Therefore, 13 patients who had not responded within two weeks had the medi-

¹ Aided, in part, by grants MY-2715 and MY-4798, National Institute of Mental Health, U.S. P.H.S. The cooperation and assistance of Geigy Pharmaceuticals is gratefully acknowledged.

³ Dept. Experimental Psychiatry, Hillside Hospital, Glen Oaks, L. I., N. Y.

cation discontinued. In retrospect, these patients had not received an adequate course of imipramine. Records were incomplete in 3 patients and at the time of writing 19 patients had not yet been discharged. These 35 patients are not included in the data analysis.

Of the 180 remaining patients, 67 were diagnosed as psychoneurotic depressive reactions, involutional melancholia, manic-depressive reaction, or psychotic depressive reaction. Schizophrenia in various subtypes was diagnosed in 102 patients. Ten patients received diagnoses of psychoneurosis or personality disorder, and one patient was diagnosed as chronic brain syndrome. Since the use of specific affective or schizophrenic subtypes was not discriminating in our analyses, the subgroups were combined.

There were 58 men and 122 women reflecting the sex distribution of the hospital. In this population schizophrenia was diagnosed most commonly in patients below 30 years of age, and affective disorders in patients above 40. However, there was no association of diagnosis or age, with sex.

Two methods of evaluating behavioral change were used—a medication management index and a discharge evaluation. The medication management index was based on the various patterns of medication use, reflecting the decision of the therapist as to the value of the medication to the patient—actions proverbially speaking louder than words. Eight patterns were observed, three implying a favorable and five an unfavorable evaluation. Favorable medication management evaluations by the therapist were seen in 115 subjects (68%) and included patients discharged to the community with the recommendation to continue on imipramine therapy (68 patients); patients discharged to the community after imipramine was discontinued with a clinical note that it had accomplished its therapeutic goals and without other somatic therapy prior to discharge (28 patients); and patients discharged to the community to continue imipramine with concurrent phenothiazine medication (19 patients).

Patterns reflecting a therapist's negative evaluation of the behavioral response were

seen in 65 patients (32%). These included imipramine discontinued and subsequent treatment with phenothiazines or convulsive therapy prior to discharge (38 patients); imipramine discontinued with the clinical note that it was ineffective and the patients discharged without further somatic treatment (19 patients); and the abrupt ending of imipramine treatment by discharge to another inpatient facility (5 patients), suicide (1 patient), or leaving the hospital against medical advice (2 patients). In this report, the first three patterns of medication use will be referred to as "favorable medication management" and the latter five as "unfavorable medication management."

In addition, at discharge each patient is given a summary rating as "recovered," "much improved," "improved," or "unimproved" by the staff. This discharge rating is a guide to the effect of hospitalization. It is not the same as the medication management index since other treatment measures may have been interposed after the imipramine treatment. However, this measure will aid in placing the imipramine effects within the context of the general hospital psychiatric treatment. In view of the small number of patients considered "recovered," this category was combined with "much improved."

The chi square method of statistical analysis was used and all stated findings are at the .05 level of confidence or better.

RESULTS

General Medication Response. The behavioral effect of imipramine required two to three weeks to become evident for the majority of cases. An occasional case responded within a few days, and one case responded after 5 weeks of medication.

Complaints of sweating, tremulousness, dry mouth, and constipation were frequent, but interfered little with the treatment course. Two patients developed grand mal epileptic attacks (at 300 mg./day and 450 mg./day) which ceased with medication reduction or termination. There was one instance of pseudo-tumor cerebri (2) and one instance of agranulocytosis. Both occurred during the concomitant administration of phenothiazines, and may have

been unrelated to imipramine.

In 22 of 26 patients receiving imipramine in 300 mg. daily doses for periods of two months or more, and rapidly withdrawn from the drug, the occurrence of a physiological withdrawal syndrome of nausea, vomiting, headache, giddiness, coryza, chills, weakness, fatigue and musculoskeletal pain was documented (7). These symptoms were related to the length of treatment and the abruptness of the withdrawal. It was also observed that these symptoms could be minimized by gradual withdrawal over one to two weeks.

Patterns of Behavioral Response. The relation of the behavioral response patterns to medication management, hospital discharge evaluation, age, sex and diagnosis are presented in Tables 1 and 2.

1. Mood Elevation Response.

Before Treatment: These patients were depressed, self-deprecatory and hopeless. Many

patients exhibited a rigid, perfectionistic and obsessional personality, although tendencies to minimize and deny difficulty were not conspicuous. They related to the examiner in an apathetic and passive fashion, although a few patients were agitated, fearful and demanding. On inquiry, they complained of anorexia, insomnia, unhappiness, loss of interest in their activities, and inability to cope with their responsibilities, to concentrate, or to make decisions. They had difficulty in staying asleep rather than falling asleep. Somatic complaints other than insomnia, anorexia and constipation would only occasionally be in evidence. However, when present they formed a major preoccupation. Suicidal ideation and frank delusional states were infrequent. These patients did not spontaneously participate in ward activities and if activity was not stimulated and guided they lapsed into apathetic indifference.

With Treatment: There was a marked decrease in expressions of disinterest in the environment, apathy, depression, suicidal rumination, retardation, agitation, insomnia and anorexia. Participation in hospital activities and

social relationships increased. Complaints of tension and apprehension relating to difficulties in discharge planning and returning to the community remained, however, with anxious procrastinating attempts to evolve a foolproof plan. Symptoms frequently increased prior to discharge.

Mood elevation was a response frequently associated with favorable medication management and hospital discharge evaluation. Special relationships to age, sex or diagnosis were not evident.

2. Explicit Verbal Denial Response.

Before Treatment: These patients closely resembled those described under mood elevation, although there was more denial and minimization of their difficulties which were usually referred to external events or bodily states rather than emotional distress.

With Treatment: As with mood elevation, depressive symptoms decreased and goal-directed action increased. In contrast to mood elevation, all complaints and difficulties were denied, the patients stating that they were entirely well and should be discharged forthwith, disregarding realistic familial and economic difficulties.

The explicit verbal denial response was generally associated with favorable medication management, an older age group, and a diagnosis of affective disorder. This group received the most favorable hospital discharge evaluations, probably as a consequence of their gross denial of residual difficulties.

Comment: These patients possessed many of the premorbid personality attributes described by Kahn and Fink(5) as characteristic of patients who responded well to convulsive therapy. Specifically, they were minimizing, denying of difficulty, non-empathic, non-introspective, communicating non-verbally, highly conventional and stereotyped.

3. Manic Response.

Before Treatment: These patients resembled closely the patients described under mood elevation response.

With Treatment: They first exhibited explicit verbal denial, but then became vociferous with a great display made of their logic as opposed to others illogic. There were periods of psychomotor acceleration accompanied by flights of ideas, loss of frustration tolerance, and lack of self-criticism. In psychotherapy, aggressive verbal attacks upon significant life

figures, most frequently spouses and mothers, became common with much talk of divorce or moving away from home. Long standing resentments, previously dealt with by submissive denial, became the focus of therapy with prominent attempts to gain the therapist as an ally against relatives. If this alliance was denied, the patient became hostile and accusatory towards the therapist. Their demanding hostility frequently led them into dictatorial, manipulative, and derogatory attitudes towards both staff and patients. They energetically participated in numerous hospital activities with great self-confidence, occasionally becoming the nucleus for a clique of hostile and negativistic patients. Delusions and bizarre activity did not occur.

Cessation of imipramine medication did not result in a reversion to their previous state, and interruption of this response by large doses of phenothiazine was usually necessary, and helpful.

Manic response was associated with a moderately unfavorable medication management. No special relationships to age, sex, or diagnosis were observed, although the 4 cases of affective disorder showing this response were diagnosed as manic-depressive disorder. There were, however, 15 other subjects with the same diagnosis who did not show a manic response to imipramine.

These patients' medication management classification as unfavorable was determined by their imipramine being replaced by phenothiazines; however, their subsequent improvement resulted in an average discharge evaluation.

4. Reduction of Episodic Anxiety Response.

Before Treatment: Typically, subjects noted the sudden onset of inexplicable "panic" attacks, accompanied by rapid breathing, palpitations, weakness, and a feeling of impending death. Their activities became progressively constricted, until they were no longer able to travel alone for fear of being suddenly rendered helpless while isolated from help. Depressive complaints were infrequent and associated with feelings of futility. Although fear of open spaces was not the hallmark of this condition but rather expectant fear of lack of support when overwhelmed, their condition was often referred to as agoraphobia. They engaged in prolonged outpatient psychotherapy, usually devoted to the exploration of unconscious sexual and aggressive impulses, with the interpretation of the phobically barred areas as situations of forbidden sym-

bolic temptation. Hospitalization occurred after the family could no longer tolerate the restrictions placed upon them.

With Treatment: Under imipramine treatment the "panic" attacks ceased, although both phenothiazines and sedatives had been previously ineffective. However, the patients were reluctant to change their phobic behavior pattern and required much persuasion, direction and support. Their social interaction increased markedly with a surprising rise in aggressive self-assertion and rejection of domination.

The reduction of episodic anxiety response was usually associated with a favorable medication management. This was the only group with a large proportion of psychoneurosis and personality disorder diagnoses. There was no special relationship to age or sex.

Comment: The reaction to imipramine is of considerable interest since the "anxiety" of the panic attack is sharply diminished while expectant "anxiety" related to the "phobic" patterns remains. The use of the common term "anxiety" may thus obscure an underlying difference in these processes.

Bowlby(3) has emphasized that separation anxiety does not have to be learned via noxious experiences of separation. In this view, separation anxiety has the biological function of evoking the retrieving and mothering response in a parent and is an innate mechanism of social control. One may speculate that imipramine, in these patients, has some specific reparative effects upon this disordered mechanism.

5. Agitated Disorganization Response.

Before Treatment: These patients were withdrawn, preoccupied, defensive, suspicious, minimizing and denying. After specific questioning they admitted to ego-alien thoughts but conveyed the impression that their hospitalization was a mistake. Their affect was flat, frequently inappropriate, and apathetic, they appeared to consciously suppress delusional material.

A history of poor social, education and vocational attainment was uniformly present, with many indications of childhood disorder.

They spoke little and by confining themselves to stereotyped utterances preserved a façade of being rational and relevant. However, any extended speech revealed peculiar and bizarre language patterns with neologisms and autistic word usage. Formal thought disorder was evident, with over-concreteness,

over-abstraction and loose associations. Psychotherapy was a barren experience as the patients made no effort to relate to their therapists and avoided any discussion of their feelings.

Social contact was actively rejected, the patients remaining isolated on the wards or roaming aimlessly about the grounds. At times they were prankish, eccentric and unpredictable and at best cooperated passively with ward routines and activities.

With Treatment: They first developed an inappropriate euphoria, which was often misinterpreted as the onset of improvement. This was soon followed by bizarre, disorganized, aggressive hyperactivity associated with intolerable tension, fragmentation of thought and marked somatic and paranoid delusions. This response uniformly required the interruption of imipramine treatment and the immediate use of convulsive or phenothiazine therapy.

Agitated disorganization was associated with a negative medication management evaluation and occurred mostly in young, schizophrenic males. This behavioral reaction was a grave prognostic sign as 58% of these patients were discharged "unimproved" and none considered "much improved" or "recovered," despite subsequent treatment.

Comment: Of interest is the marked similarity of this group of patients to those described as having the reaction pattern of autistic compliance to phenothiazines(6). The predominance of males is similar to the sex ratio of childhood schizophrenia.

6. Anhedonic Socialization.

Before Treatment: These patients related to the examiner in a discouraged and dependent fashion with manipulative tendencies. They spontaneously grumbled of an anxious depression, also the observed affective display was less than the extensiveness of their complaints. These complaints concerned fluctuating feelings of withdrawal, anxiety, tension, depression, depersonalization, phobic compulsions, ruminative thoughts, and inertia. A lack of feelings of pleasure and competence was prominent.

They were rational, relevant and coherent, and described their complaints in abstract psychiatric terms. It was difficult to obtain a specific connected story concerning their symptomatology. If the psychotherapist indicated certain strengths, this was immediately met by a burst of self-derogatory expressions. Many of these patients had previously received pro-

longed outpatient psychotherapy.

They associated with similar patients in tight cliques, preserving a friendly relationship. While few of the hospital activities were interesting to them they stayed active rather than withdrawn. They frequently had a history of good social and educational achievement marred by a pervasive anhedonia.

With Treatment: This group manifested an increase in alertness, definiteness and precision. Dependent demands were diminished. Their verbal affective complaints were modified only slightly, although they appeared to be less anxious and depressed. Symptoms of apathy and inability to function were alleviated, while feelings of depersonalization, phobic compulsive and ruminative thoughts were maintained. The effects of the medication were minimized by the patients, yet their symptoms exacerbated on medication withdrawal.

In psychotherapy a degree of overt self-assertion became apparent, associated with some guilt and apprehension over aggressiveness. They became more active, dressed more attractively and associated with more people, achieving responsible positions in their ward or peer group organizations. Hospital activities were utilized more fully and in a more interested fashion.

This response was associated with a favorable management evaluation. This group consisted of young schizophrenic patients without relationship to sex distribution or hospital outcome. The only suicide in this study occurred in this group.

7. Non-Responding Patients.

No significant behavioral changes were observed in 40 patients. In pretreatment characteristics, these subjects were classified into a few subgroups.

A group of 13 patients showed histrionic labile affect, with depressive, fearful, paranoid and agitated displays rapidly alternating with affable friendly periods. Their lability made evaluations of drug effect very difficult, requiring long observation periods before an evaluation could be made. The histrionic manipulative character of these patients gave the impression that their affective displays were goal-oriented and ludic devices for manipulation of the environment rather than direct expressions of internal distress. Phenothiazine medications were also ineffective in modifying their behavior.

Other patients had a variety of syndromes with the common thread of marked fixity of symptomatology over a period of years prior to hospitalization. These syndromes were so-

matic preoccupation (10 patients), obsessional rumination (6 patients), fearful paranoid referential states (4 patients), and a variety of schizoid and psychopathic character disorders (7 patients). Phenothiazine medications were also ineffective in modifying their symptoms.

The "non-responders" were preponderantly female without a special relationship to age or diagnosis. Hospital outcome was poor.

Relation of Age and Diagnosis to Medication Evaluation. By grouping the subjects according to medication management, age and diagnosis, we observed that the percentage of favorable medication management is approximately 51% for schizophrenia, and 79% for affective disorder, at all age levels. We would conclude that diagnosis is more closely related than age to clinical evaluations of imipramine therapy.

CONCLUSIONS

Imipramine appears to be a safe and valuable medication in the treatment of a variety of psychiatric conditions. It produces various behavioral change patterns that are related to both the personality of the patient and the symptom pattern of the illness. While these response patterns cut across the usual nosologic categories, there is a significant statistical relationship to the distinction between schizophrenic and affective disorders. These patterns of behavioral response are highly associated with pretreatment behavioral patterns, and further study may serve to define subgroups whose response to imipramine can be predicted with high probability.

Similar observations are reported by Ayd (1) in a review of the current status of the "major antidepressants." Allowing for differences in terminology, his findings closely parallel our own. For example, Ayd notes:

Dramatic therapeutic results were seen in those patients often diagnosed anxiety hysteria because their depression was overshadowed by severe anxiety with hysterical features. [They] . . . had good pre-illness personalities despite an anxious, phobic temperament. In contrast to the classical endogenous depressive, these patients had a normal sleep pattern or insomnia, which readily responded to barbiturate hypnotics, rather than an early morning awakening. Usually they complained of feeling

worse as the day wore on. They had little appetite disturbance and no great weight loss. They had many somatic complaints. Seldom were they self-depreciatory. They detested being alone, were voluble, anxious, and tremulous and exhibited psychomotor stimulation instead of inhibition . . . Tranquilizers invariably made them feel worse, ECT enhanced their anxiety . . . When treated with an antidepressant they reacted promptly . . .

The personality organization and behavioral response of these patients are strikingly similar to those described as showing a reduction of episodic anxiety response to imipramine.

This response was seen by Ayd as indicating that in these patients "depression was overshadowed by severe anxiety." In similar fashion, others have referred to "underlying" or "masked" depressions. The basis for these formulations appears to be the positive behavioral response to "antidepressants," as the classical signs and symptoms of depression are not clinically manifest. Yet, these patients are refractory to convulsive therapy, which should lead to the inference that they do not have an "underlying" depression.

Such terms represent *ad hoc* formulations that obscure common characteristics distinctive in these patients. In an earlier study (6) we indicated that the behavioral patterns after phenothiazine medication are related to the antecedent behavior, as seen in characteristic adaptive mechanisms, communication patterns, affect, symptoms, psychotherapy participation and social activity. The responses to medication may be used as dissecting tools to uncover various subpopulations and to permit the discovery of specific developmental, physiological, psychological and social similarities within each subpopulation. These common characteris-

tics may also clarify questions of etiology and pathogenesis of psychiatric disorders, and provide rational indications and contraindications for drug therapy. The observations with imipramine reported here suggest that these generalizations may be true for a wide variety of psychotropic agents.

SUMMARY

1. One hundred and eighty voluntary inpatients (102 schizophrenic subjects, 67 subjects with affective disorders, and 11 "other" diagnoses) were studied during treatment with imipramine.

2. Seven imipramine induced behavioral reaction patterns and their relationships to diagnosis, age, sex, patterns of medication use, and hospital discharge evaluation are presented. These include mood elevation, explicit verbal denial, manic, reduction of episodic anxiety, agitated disorganization, anhedonic socialization, and non-response.

3. Imipramine was favorably evaluated in 79% of subjects with affective disorders and 51% of schizophrenic patients.

4. The use of psychiatric reaction patterns to psychotropic drugs for categorizing patients and providing a basis for a more rational pharmacotherapy are emphasized.

ABNORMAL STATES OF CONSCIOUSNESS AND MUSCLE TONE IN INFANTS BORN TO SCHIZOPHRENIC MOTHERS¹

BARBARA FISH, M.D., AND MURRAY ALPERT, M.S.²

In studies conducted since 1952 by one of the authors (B.F.), it has been possible to observe neurological deviations as early as 1 month of age in infants who later became childhood schizophrenics (6-8). The age when the transient disorganization of neurological development was the greatest varied from one child to another, producing different patterns of assets and handicaps. In some, a lag or peculiar sequence in postural or locomotor development was the most prominent; in others, confused proprioception and perception of form occurred before the onset of distorted language and social relationships. Several of these infants retained an abnormal torpid state of consciousness, remaining inactive and unresponsive, with a flaccid muscle tone in their first months of life. Others became inactive, toneless and apathetic when their development lagged or regressed at about 1 or 2 years of age (8, 10). Data on older schizophrenic children suggested that severe hypoactivity and apathy are signs of a severe disturbance that frequently ends in grossly defective intellectual and social development (9-11). The severity of the lags and disorganization varied from child to child and was expressed quantitatively by a detailed assessment of developmental progress. In general, when the early neurological disturbances were the most severe, there was greater interference with intellectual and social adaptive functioning, and less capacity for defense formation (10, 11). It was hypothesized that these transient neurological disturbances are earlier manifestations of the same underlying disorder

of integration that is manifested in adult schizophrenia by the disorganization of complex psychological functions (8). The different clinical manifestations of early childhood schizophrenia were viewed as variations on the common theme of a basic disturbance in neurological development.

In order to extend these observations, an infant population was examined which was genetically loaded for schizophrenia and which was expected to show a higher incidence of developmental disorders. Neurological and psychological development were followed, using the methods of the earliest infant study (6, 7). In addition, vestibular function was tested and methods were developed for characterizing states of consciousness.

A study of consciousness in infancy is limited to objective measures of the sleep-waking continuum. For this study, a behavioral continuum was defined, which ranged from deep sleep through alert attentiveness to extreme excitement or crying, with 3 intermediate steps (restless sleep, open-eyed drowse and restless wakefulness with slight whimpering). Within this arousal continuum, the infant is most accessible to environmental stimuli when he lies quietly with his eyes open, alert to visual stimuli. Accessibility is reduced if he is less aroused, being sleepy or drowsy, or if he is more aroused, becoming restless or vigorously crying. This continuum was later found to be similar to the behavioral continuum of arousal which Lindsley related to gradations of awareness and to levels of activation on the EEG in adults (17). The ability of the infants to maintain a stable state of optimal alertness was analyzed as a function of age. This followed the approach used in the earlier studies of schizophrenic infants, in which deviations of various neurologic functions were defined in relation to established age norms (2, 7-11).

All infants born between March, 1959 and September, 1960 to patients in two New

York State mental hospitals were included in the study. All mothers had been diagnosed as schizophrenic by the hospital staff. They had been ill for periods ranging from 6 months to 20 years. Most mothers had no phenothiazines for 1 to 3 months prior to delivery.

The infants were examined on the first day of life, usually between 12 and 24 hours of age; on the fourth day of life; and again at 1, 2, 3, 4, 7, 10 and 13 months of age. Thereafter, they were seen yearly, as long as follow-up could be continued. Two infants were lost to follow-up after the initial examination in the nursery. The remaining 13 have been followed for 10 to 24 months. Nine are in foster homes, 3 with their grandmothers, and 1 is in a foundling institution.

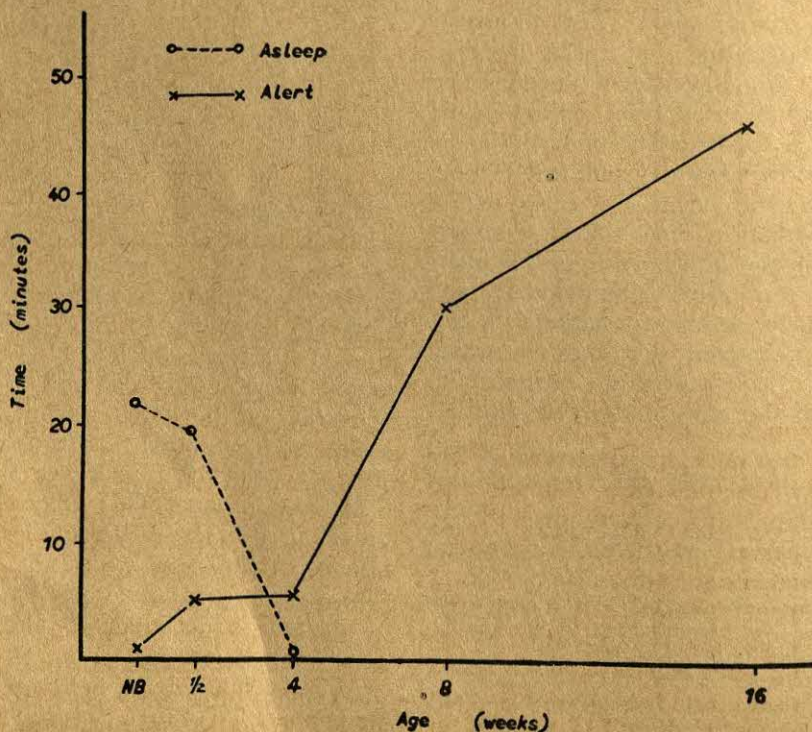

Infants were examined between 1 and 2 hours after the last feeding. In addition to the Gesell examination(13), the examination was composed of a series of stimuli graded from the mildest, *e.g.*, voice, test of

visual following, touch, to the more strenuous, *e.g.*, pinprick, postural manipulation, and caloric stimulation to elicit nystagmus, presented in that order. Throughout the 1½-hour examination, a continuous time record was kept, noting when the child had his eyes open or closed, when he cried, whimpered or moved, and when a pacifier was required.

RESULTS

General Trends. When the data were analyzed for the pattern of consciousness at each examination, several measures defined the progression of the group toward a stable state of optimal alertness with advancing age. The median time spent quietly asleep during initial stimulation (before the onset of sustained crying for a minimum of 2 minutes) dropped from 20 minutes on the first and fourth days of life to 0 at 4 weeks of age (Fig. 1). The sleepy state became negligible after the fourth day, when the majority of infants recovered from

FIGURE 1
MEDIAN TIME ASLEEP AND QUIETLY ALERT
DURING EXAMINATION

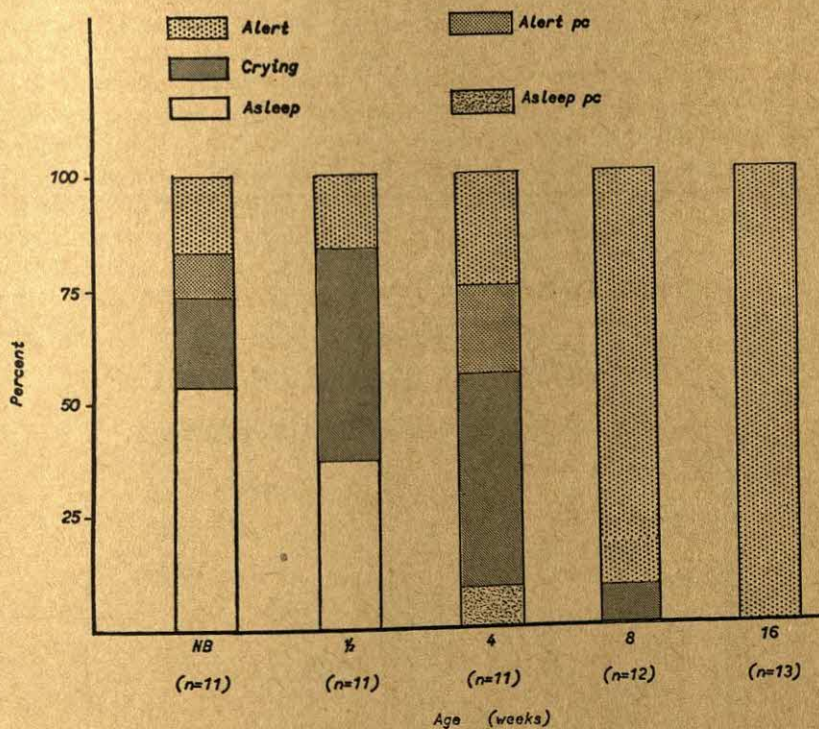

obstetrical analgesia and the birth process. The median time spent quietly alert increased sharply between 4 and 8 weeks of age, from less than 5 minutes to 30 minutes, and it continued to increase thereafter (Fig. 1).

Between the sleepiness of the newborn period and the alertness at 8 weeks of age, there was a period in which the infant usually cried if he awakened spontaneously or after stimulation. This is reflected in the change in the baseline state which occurred with age (Fig. 2). The baseline state

infants who sustained open-eyed alertness gradually increased to 90% by 8 weeks of age. By 8 weeks almost all infants were able to maintain an optimal level of responsiveness to external stimuli, without dropping off to sleep or quickly shifting to sustained crying. This maturation is also reflected in the maximum time during which the infants could continuously sustain optimal alertness (Fig. 3). The median time for maintaining continuous open-eyed alertness increased from only 2 to 5 minutes between birth and 4 weeks of age, to 25 minutes at

FIGURE 2
INCIDENCE OF DIFFERENT BASELINE STATES AT EACH AGE

was defined as that level of arousal to which the infant spontaneously returned after being aroused just enough to test vision. (Except in the sleepy newborns, this required only mild stimulation or none at all, if the infant was already awake.) The majority of infants were sleepy on the first day, but very few remained so after the fourth day. The number of infants who cried when awake unless given a pacifier increased after the first day of life, and then dropped sharply after 4 weeks of age. The number of

8 weeks, and it continued to rise thereafter to 45 minutes at 16 weeks, and still longer in the older infants.

The marked increase in alertness at 8 weeks reflects the capacity of the CNS to organize and maintain stable states of alertness. Another aspect of this increasing integrative capacity is seen in the drop in the median number of fluctuations of the state of arousal during examination (Fig. 4.) Many more fluctuations of state are apparent in the earlier examinations. This gross

FIGURE 3

MAXIMUM TIME CONTINUOUSLY ALERT

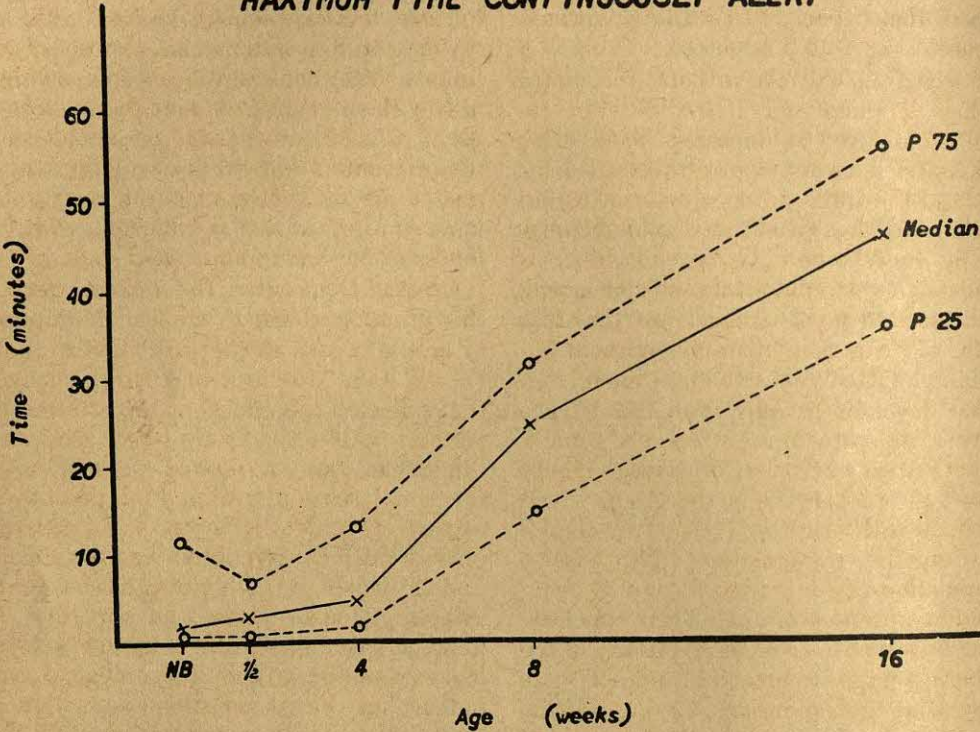

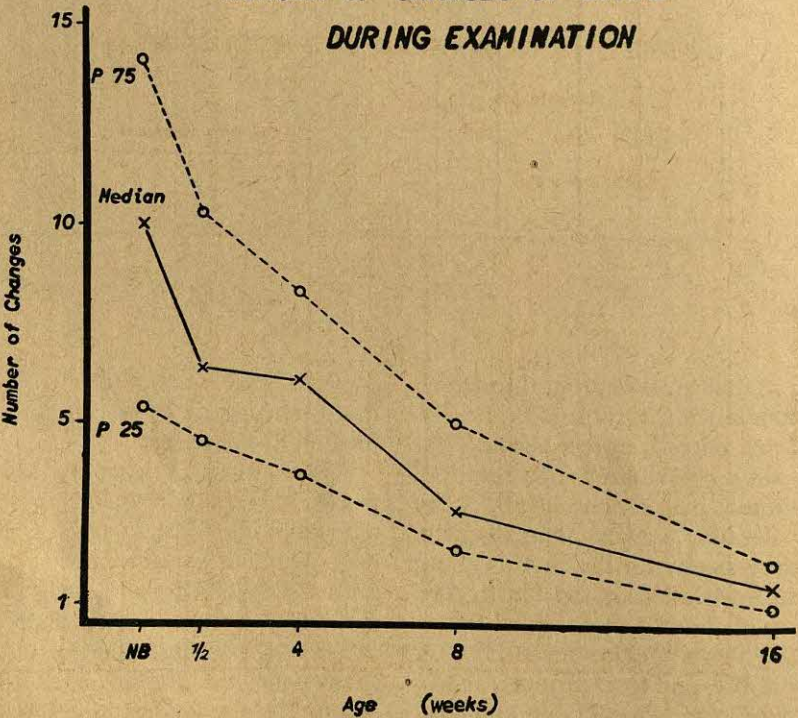

FIGURE 4

NUMBER OF CHANGES OF STATE DURING EXAMINATION

measure of instability of arousal state gradually declined with age, as the infants developed the capacity to sustain optimal alertness.

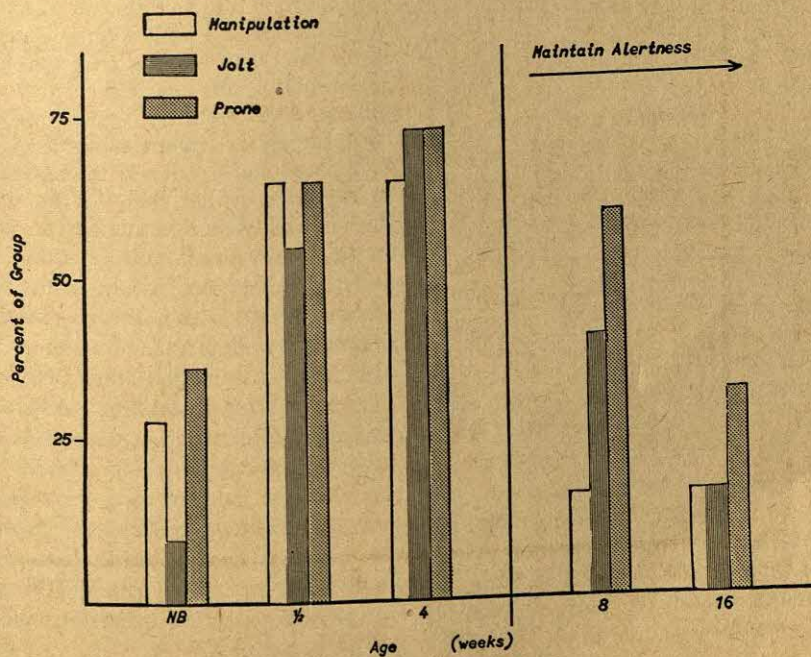

As seen from the above data, the infant develops an increased accessibility to external stimuli as he matures. Soon after birth, as he recovers from obstetrical analgesia and the birth process, he can sustain a high level of arousal after mild stimulation. By 8 weeks he develops the ability to modulate the extreme excitability or crying which accompanies arousal in the first month. He can then maintain optimal accessibility. This capacity for modulated arousal develops parallel with the infant's ability to tolerate more strenuous stimuli, without excess excitation or crying. Figure 5 shows the percentage of the group which responded with sustained crying to each of 3 items on the examination (jolt, passive manipulation of the extremities, and being placed in a prone position). There was little crying in response to postural stimuli in the newborn period, when the infants were sleepy and unresponsive. Crying during postural tests increased at 4 days and 4 weeks, along with the other signs of in-

creasing arousal and excitation noted above. After 4 weeks of age, the infants began to tolerate these strenuous stimuli with less crying. At 8 weeks, when almost all the infants (90%) could sustain open-eyed alertness without crying, we note that almost all could also tolerate passive manipulation of the extremities without crying. This may be related to their toleration for their spontaneous arm and leg movements, with less tendency to shift to an excited state.

Clinical Deviations. The median trends in this group conform to clinical descriptions of arousal states in the first months of life (5, 12, 14). Measures of central tendency that reflected the effects of the extreme deviations within this group might well show differences from a normal population. In this small, selected group, 3 infants showed excessively quiet behavior, with extremes of underactivity, hypotonia and absence of crying, which are highly unusual for young infants. A fourth showed an abnormal degree of irritability, and 3 infants showed less extreme deviations. These clinical evaluations are based on the examination of large numbers of normal infants (B.F.), but no exact comparison with an unselected

FIGURE 5

PERCENT OF GROUP CRYING WITH MOTOR STIMULI

group is possible, since comparable quantitative data are not yet available. However, the gross behavioral measures of arousal in this study do make it possible to define some of the differences between these deviate infants and the rest of the group.

The 3 most extremely quiet infants differed primarily from the rest in their ability to maintain a baseline state of quiet, open-eyed alertness as early as 13 hours of age. One resembled the other infants by 4 weeks, but the other 2 were always quietly alert and never showed the baseline state of crying with arousal. These infants could remain quietly alert for 15 to 80 minutes during stimulation in their first month of life, in contrast to the median of 2 to 5 minutes. Unlike the other infants, they also tolerated vigorous manipulation of joints and muscles without crying.

"Charles," the most extreme example of this, was excessively quiet for his first 6 months of life. He was markedly underactive, lay still and quietly alert, and tolerated vigorous manipulation of muscles and joints, jolt, and change of position without crying. However, he followed visual stimuli normally as he developed, and was extremely alert to slight sounds and touch. He cried sharply and briefly with a light pinprick. He was therefore selectively unresponsive to proprioceptive stimulation, compared to other stimuli. His muscles were extremely doughy to palpation, feeling indistinguishable from soft subcutaneous tissue. Although his head control was normal for his age, his trunk and extremities were so flaccid that he could be folded or twisted like rubber to bizarre, extreme positions without showing any increase in tone or signs of discomfort. The nursing staff spontaneously and affectionately nicknamed him "Floppy"; "He's like a little rubber doll." His poor tone interfered with his early grasping and reaching, and caused a marked delay in sitting (less than 4 months' level at 6 months of age). However, he rolled and pivoted like an 8-month-old when he was only 4 months of age. Unlike hypotonic infants with peripheral neuromuscular disorders (19), his deep tendon reflexes were 3+, loose and pendular. His hypotonia was apparently of central origin.

Although he was placid and inactive, he remained very socially responsive and vocalized after 3 months of age. At 6 months, he showed a marked spurt in postural control, and by 7 months he was able to sit and creep

like a 10-month-old. Shortly after this, the tone of his legs improved, and locomotor development advanced so rapidly after 10 months that he could walk, run and climb stairs like a 21-month-old by the time he was 14 months. At 6 months the foster mother felt he "showed no spirit," but his self-assertion increased along with his motility, and she noted at 1 year that she could "hardly keep him down." During this period of his most rapid development around 1 year of age, it was noted that for several weeks he became afraid of all cats, dogs with dark fur, and of people wearing dark clothing. These symptoms, associated with his increased assertiveness apparently, gradually subsided after 13 months of age.

He has been hyperactive and impulsive since 14 months of age. Daytime fears and tantrums and severe screaming spells at night, accompanied by headbanging, occurred periodically from 12 to 18 months, and then gradually subsided. He is still considered willful and sensitive, but tantrums are brief and no longer occur daily.

The 2 irritable infants differed from the group by continuing to cry with muscle and joint manipulation long after 4 weeks of age, when the other infants tolerated these stimuli. They showed a baseline state of sustained crying whenever aroused after 4 weeks, and could maintain a quietly alert state only for brief periods.

The most irritable infant, "Rachel," showed the most severe psychiatric disorder of the entire group at 2 years of age, despite the ministrations of a very calm and understanding foster mother. In her first week, the only abnormality noted was her slow, stretching, athetoid-like motility, which resembled that of a premature infant more than a full-term baby, and her tendency to maintain her legs in extension rather than in the normal semiflexion. She was unusually responsive to tactile, proprioceptive and auditory stimuli from birth, and continued to startle with minute and distant sounds. From 1 to 6 months, she had difficulty swallowing and vomited frequently, although examination disclosed no organic pathology. Her irritability persisted, and she was unable to sustain attention as long as the other infants. Apparently related to this, her visual-motor performance has been retarded and poorly integrated since 7 months of age. At 2 years, her excessive fear and freezing with any new stimuli resulted in grossly maladaptive functioning in performance tests and social behavior.

CONCLUSION

The evaluation of the changing pattern of consciousness can be used as a measure of the growing integrative capacity of the central nervous system in infancy. In the first months of life, at least two skills develop which are necessary for the maintenance of the quiet, open-eyed alert state. There is an increased general level of arousal(17) sufficient to permit responses to minimal visual and auditory stimuli. There is also a gradual modulation of spontaneous excitability and an increase in the toleration of proprioceptive stimuli. This permits a continuing stable state of awareness and prolonged, focused attention. These abilities are essential prerequisites for the well-integrated development of specific alerting responses(17), which involve differentiated attentiveness, perceptual discrimination, patterns of accommodation, and the more complex functions which modify the accessibility of the CNS to different stimuli.

The organization of a stable, sustained state of alertness by 8 weeks of age, as measured in a standard sample of timed behavior, precedes the organization of consolidated waking-sleeping patterns in 24-hour behavior samples(12, 16, 18). It also antedates the qualitative increase in organization noted in infants' EEGs at 3 months of age(3, 4).

As part of an ongoing study into abnormal development and early schizophrenia, consciousness and sensory responsiveness were studied in infants of schizophrenic mothers. Four infants showed marked deviations in the direction of excessive apathy or irritability. At 2 years of age, only the most irritable infant has shown grossly maladaptive behavior. The quiet infants had attenuated motor impulses, minimal response to proprioceptive stimuli, and in the most extreme case, flaccid muscle tone and irregular postural development. This quiet state clinically resembles the "adynamia" which Hess produced in cats by electrical stimulation of the lateral anterior hypothalamus(15).

These deviations in the state of consciousness, motility and muscle tonus as early as the first day of life, and continuing into the

early months of infancy, provide additional evidence of some early disturbance of functioning of the nervous system in this population, which was genetically loaded for schizophrenia. It is postulated that these dysfunctions are related to the disturbances of motility, excitability and perception which are seen in older schizophrenic children (1, 8).

FAILURE TO KEEP APPOINTMENTS WITH THE ARMY PSYCHIATRIST: AN INDICATOR OF CONFLICT

L. JAMES GROL, CAPT., M.C., AND WILLIAM G. HILL, CAPT., M.S.C.¹

Civilian psychiatrists commonly encounter difficulty in ascertaining why some patients who are referred for consultation either do not appear for their appointment or do not return after the first visit. Lacking information other than that obtained from the referral source or from the single interview, the psychiatrist may conjecture that the patient's failure to keep his appointment results from a lack of motivation, resistance to making changes, or inadequate rapport. Usually the psychiatrist is unable to investigate the circumstances involved.

The Army psychiatrist, however, because of the circumscribed nature of the military community and the readily available channels of communication, is able to clarify some of the reasons for this common occurrence.²

For this purpose the January-June 1961 records of a division psychiatric section were reviewed. This inquiry revealed that over 35 individuals each month failed to keep appointments; 3 of every 4 of these men had been referred for possible psychiatric treatment.

Since this division is in a constant combat-ready status, the units comprising the division and their dispensaries are tactically separated at a considerable distance from the psychiatric section, creating transportation difficulties. This situation plus the frequent field training problems could account for some of the failed appointments. However, since the patients are commanded to appear for the scheduled psychiatric consultations, these factors alone did not seem sufficient to account for the total number of missed appointments.

From contacts with the individuals re-

ferred, the units to which they were assigned, and the referring source a variety of explanations were obtained. The patient had been transported to the wrong place or had missed the only available transportation. The patient had been given an assignment which prevented him from arriving at the psychiatrist's office. There was a misunderstanding as to the time of the appointment. The individual felt he had resolved his difficulties and did not desire further assistance.

Closer inspection revealed that these explanations were inadequate. For example, though a unit might not have transportation available at a given moment, two blocks away a scheduled bus left from the unit dispensary where the referral had originated. In another instance, the patient travelled to a different location even though he had been seen by the psychiatrist previously. Another patient was placed on guard duty although his unit was aware that the dispensary doctor had made an appointment for him to be seen in the psychiatric section.

To understand these discrepancies, further discussions were held with individuals referred, the officers and men of the units, and the referral sources. Three interrelated groups of attitudes toward the psychiatric patient and the psychiatric service were revealed: the attitude of the individual patient, of the officers and other men of his unit, and of the referring source(1).

Attitudes of the Patient. The source of some individuals' misconceptions of the military psychiatric patient and the psychiatric service is partially attributable to the belief that the historical image of the psychiatrist, as one who provided custodial treatment for severely disturbed patients, has not changed with time.

K. was referred by his unit commander because of irritability which had resulted on several occasions in K.'s throwing his boots through the barrack's windows. K. presented himself early at the psychiatric service, but

¹ Headquarters, Third Armored Division, Office of the Division Surgeon, APO 39, New York, N. Y.

² Although this study was executed in a single setting with certain unique characteristics, many of the observations have been substantiated in other division mental health clinics. The previous experience of one of the writers at a stateside military mental hygiene clinic also supported conclusions drawn from this study.

when his appointment time arrived he could not be located. A contact with his unit revealed that K. had returned to notify his superior officer that he was not "crazy" and did not need to return to the clinic.

From further discussion, it was learned the individual viewed his commander's referring him to the psychiatrist as equivalent to being considered "crazy." To him this implied incurability and commitment to a psychiatric hospital.

In addition to having confused notions as to the type of patients treated by the psychiatrist, most individuals had little understanding of the psychiatrist's functions, limitations, or capabilities (2). One patient's lack of understanding of the function of the military psychiatrist resulted in severe disappointment when his unrealistic expectations were not fulfilled.

A. arrived at the psychiatric clinic complaining of dissatisfaction with his unit. He felt that officers were prejudiced in that they had not allowed him special privileges and limitations of routine duties, considering his "superior intelligence and two years of junior college." The solution, he felt, was a transfer to a "less narrow-minded unit." He stated his sole purpose in coming to the clinic was to solicit aid in effecting this transfer. The clinic's limitation in accomplishing this transfer was discussed with him and further appointments were offered in order to discover other solutions which might be feasible. He reluctantly accepted another appointment but did not return.

This man's reluctance to accept any personal responsibility for his present difficulties contributed to his unwillingness to return. He represented a large number of referrals who conceived the only value of psychiatric assistance to be some modification of their environment, such as relief from extra duties, transfer to a different unit, obtaining a different job, being given a military discharge, or other type of administrative change. The unlikelihood of such a manipulation of the person's environment resulting in a satisfactory solution, plus the many administrative limitations frequently resulted in disappointed individuals who failed to return a second time.

The military community often requires

the psychiatrist to make recommendations which may become the basis of administrative actions. This responsibility may interfere with the patient's willingness to divulge personal problems for fear that any written evaluation may become common knowledge, or in some way affect promotions or performance ratings. Both officers and enlisted men have expressed their reluctance to return after an initial appointment because of these fears.

Another source of conflict develops when the individual considers his referral to the psychiatric service to be for a concealed reason, such as a surreptitious evaluation preliminary to an administrative discharge. A man who is performing his work satisfactorily may be quite hesitant to accept a subsequent appointment if he thinks that a psychiatric consultation may precede a recommendation for an administrative discharge.

Attitudes of Officers and Men of the Unit.
An evaluation of the appointment failures revealed a disproportionately large number in some units. No relationship could be established between the number of appointment failures and the unit's distance from the psychiatric section, its size, or the amount of time spent on maneuvers. However, a high number of appointment failures did correlate with a low percentage of requests for psychiatric consultation by the unit and with a disproportionately high rate of unit disciplinary problems as reflected by numbers of administrative discharges.

The underlying attitudes of the officers and men of these units were studied more intensively. It was learned that when an officer in one of these units viewed the psychiatric facility as solely a way station in the administrative process for the elimination of undesirable persons, he tended to hinder individuals who were not obvious disciplinary problems from seeking help.

E. was admitted to the hospital for immediate lifesaving surgery after he had thrown himself out of a third story window. The officers of his unit had been aware of his many problems for a number of months and had expended considerable effort in attempts to assist him. When one of the officers was asked, after the suicidal attempt, why E. had not been referred to the psychiatric clinic, he said, "E.

was a fine soldier, not a trouble maker ; why should I send him to the psychiatrist ?”

Other commanding officers felt that the psychiatrist could offer them little assistance in the rehabilitation of disciplinary problems. These officers concurred that their men with behavioral disturbances could best be “rehabilitated” if they were given long sentences in the stockade. Punishment, not insights into their men’s difficulties, was considered the better solution.

Some of these commanding officers’ attitudes were reflected in their delaying the referral of overtly psychotic individuals to the psychiatrist.

B., a 25-year-old, was observed by his superiors for 4 days to be hallucinating conversations with elephants. On the 5th day, after he had been repeatedly told to “stop faking,” he was transferred to a new unit where he was finally referred to the psychiatrist.

It was later learned that this commanding officer viewed B.’s symptomatic disturbance, which had not been improved by his usual techniques of “counselling,” as a failure of his ability as a leader. Not wishing his feared deficits to be exposed and not wishing his prerogative as an officer to be appropriated by an outside source, he had not referred the man for psychiatric consultation but preferred to transfer him instead.

One week later this same officer demanded immediate cure of an alcoholic that he had unsuccessfully ordered to stop drinking and had punished over the past 8 months. The patient, who arrived for the initial appointment, expressed no desire to return or to modify his behavior. He had come only because of his commander’s order. Frustrated by this alcoholic’s lack of improvement and guilty over his having delayed the request for professional advice, this commander demanded a magical instantaneous solution from the psychiatrist.

Some units, disturbed by the potential psychiatric patient, utilized many direct and indirect measures to prevent the patient from continuing with his appointments.

O. came to the clinic because of mild depression, recurrent nightmares, and fears of the dark. After failing the second appointment, O. was seen at his unit by one of the authors.

He stated that he did not want to return because on the day of the second appointment, his name had been called at the morning formation as having an appointment with the “head shrinker” that afternoon. This announcement was followed by considerable laughter among the other soldiers. Some of them commented, “O. must be a nut,” and “That’s a bugout for you.”

The stigma of these labels, the unwanted ridicule and derision of his fellow soldiers contributed to his not returning. More direct measures were used with T.

The unit surgeon referred T. because of depression, difficulty sleeping, and fears of the dark. After he had failed to keep his appointment, the unit was telephoned. The first sergeant stated that T. could not keep his appointment because he had been placed on guard duty. Furthermore, the sergeant felt that T. was “only faking” and not really in need of help.

An officer, concerned that he might be criticized for his past treatment of one of his men, became more lenient once the individual had been referred to the psychiatric section.

P. came to the clinic on referral from his unit surgeon with a problem of excessive drinking and depression. His unit was aware of his drinking as he had failed to show up for work several times after all-night drinking sprees. During the first interview P. explained that since he had not been given sufficient authorized leaves he was drinking excessively. After P. failed to arrive for his second appointment, it was learned from his unit that P. was no longer depressed and had stopped drinking. He had been given unlimited pass privileges and had been taken off extra duties. The unit explained that they had decided to give P. “a break” now that he had become a “psychiatric case.”

Forces were mobilized by this group as soon as they had accepted this individual as a psychiatric patient. If these processes had not been known to the psychiatrist, this individual’s symptomatic improvement or worsening might possibly have been attributed to some kind of psychotherapeutic intervention.

Either being referred to the psychiatric section or behaving in a sufficiently bizarre

manner may result in an individual's being designated as "emotionally sick" or "crazy." The unit then considers the individual to be not completely responsible for his actions and will treat him with a more lenient, outwardly tolerant attitude and demand less of him.

If the individual is not hospitalized after the initial psychiatric appointment, this may be interpreted to signify that he is not "crazy" and, therefore, does not require additional visits. In several instances, unit officers were apparently quite pleased to have their diagnosis of "not crazy" confirmed by the psychiatrist. Relieved of any guilt feelings, the officer felt sanctioned to punish the individual for his misbehavior.

Attitudes of Referral Sources. As in civilian practice, the method of psychiatric referral can materially affect the patient's expectations and attitudes prior to his ever entering the psychiatrist's office(3). The major difference between civilian and military practice results from the possibility that the soldier who is reluctant to be seen by the psychiatrist can be ordered to appear against his wishes, although he may not voluntarily return a second time.

C. was referred by his dispensary doctor because of numerous somatic complaints (headaches, backaches, and stomach pain) for which no organic cause could be found. On the date of the consultation, C. went AWOL. On being seen at a later date after his apprehension, C. said that he was not "crazy." He wondered why his doctor had referred him to the psychiatrist.

Attitudes toward the psychiatric section held by the various referral sources may contain any of the previously described elements found in the other groups.

S. related that he had been trying to come to the clinic for over three months. He had talked with the chaplain and with his unit surgeon about his many worries. On these occasions he had been told it was not necessary to be seen by the psychiatrist, that he "should not let things worry him" and that what he needed was a few days leave. On the first day of leave, he came to the clinic on his own.

Attitudes of the Psychiatric Service. The attitudes of the psychiatrist, which are

conveyed to the patient during the initial interview, are more difficult to assess. A patient's failure to return undoubtedly may stem from the psychiatric worker's insensitivity to the patient's anxieties or an inability to develop the necessary atmosphere of acceptance and understanding. Since the majority of the enlisted men who comprise the bulk of the psychiatric referrals come from a lower socio-economic background, it is not surprising that many patients might feel "misunderstood" by the psychiatric staff, whose values and backgrounds are often quite different(4).

DISCUSSION

The study indicates that reluctance to take advantage of psychiatric assistance is related to the individual and group images of the psychiatric section and the psychiatric patient. Misconceptions about psychiatric patients and psychiatry are derived from a variety of fears, attitudes, and unrealistic expectations of the individual patient, the referral sources, and the patient's unit, which can and do conflict with one another. The end product of these conflicts is that the patient fails to be given or to keep an appointment.

Of considerable concern to the mental health worker is the modifiability of these group attitudes. In this setting, as a result of knowledge gained from this study, face-to-face discussions with unit commanders and sources of referral have increased.

As the attitudes of the units and referral sources toward psychiatry and the psychiatric patient change, the military group becomes less threatened by deviant patterns of behavior. Individuals are referred for psychiatric consultation with more appropriate expectations, appointments are infrequently delayed, and patients rarely fail to keep appointments once made.³

What accounts for this reduction in the number of missed appointments? As information is exchanged between the psychiatric section, the units, and referral sources, misconceptions and distortions are reduced. The psychiatrist begins to recog-

³ Following this exploratory study, it was found that although the case load had doubled, there were only 15 individuals each month failing to keep appointments.

nize the complex group tensions which necessitate a group evaluation prior to making an individual diagnosis. The referral sources, military units, and psychiatric section become familiar with mutual problem areas and explore possibilities for cooperation. Knowledge of group processes, which perpetuate an individual's pathology or prevent his return to the psychiatrist after an initial appointment, aids the psychiatrist in making an adequate assessment of the individual, and appropriate recommendation increases, in time, the unit's confidence in the psychiatrist.

Our experience has been that adequate early evaluation and supportive treatment by many para-medical personnel is already available at the unit level if they are advantageously employed and work harmoniously with the psychiatric section. The stigma of mental illness associated with seeing the psychiatrist can be reduced by supporting and advising the dispensary doctors, chaplains, company commanders, Red Cross workers, and other auxiliary personnel in their work with disturbed individuals often without the psychiatrist ever seeing the individual personally.

SUMMARY

An investigation of failures to keep appointments and reluctance to refer individuals in obvious need of psychiatric assistance was conducted in an Army division psychiatric section. Making use of formal and informal channels of communication within the military community, the investigators were able to explore the basic question of failure to take advantage of the mental health facility.

The study indicated that several inter-related factors appeared to be associated with the problem: 1. The attitude of the

individual patient; 2. The attitude of the group within which the individual lived and worked; and 3. The attitude of the origin of the referral. These three sources contained a variety of fears, unrealistic expectations, and misconceptions about the psychiatric service. Where conflicts arose as a result of these misunderstandings, the end product was the failure to utilize the mental health facility.

Because of these discoveries, a more intensive educational program and an increase of primary contacts with sources of referrals and units within the division were made. These efforts have resulted in a dramatic decrease in the number of appointment failures and an increase in new referrals.

Even though this study was conducted in a military rather than a civilian setting, it appears the knowledge gained has applicability to both. It seems evident that consideration must be given to those forces outside the psychotherapeutic process which impede the use of available psychiatric assistance. Of equal importance is the necessity for the psychiatrist to be aware of the basic problem of failure to keep appointments in his own community and to ascertain what courses of action he might take to reduce these conflicting attitudes.

AKINETIC MUTISM SIMULATING CATATONIC SCHIZOPHRENIA

JOHN A. SOURS, LT. (MC) USNR^{1, 2}

Akinetic mutism, a state of altered consciousness well described by Cairns, *et al.* (1), in 1941, is now recognized as a syndrome with clinical features including mutism, varying from unreactive coma to somnolence and pseudo-wakefulness, immobility except for eye movements, and obnubilation. Such a patient is often easily aroused, follows moving objects with his eyes, gives a suggestion he will speak and is apt to follow commands slowly but incompletely. The akinesis may be broken by a sudden outburst of restlessness or general hyperkinesia. Through visual and auditory commands, communication cannot be established, although there may be selective responses. He may voluntarily withdraw on painful stimulation. He gives no real indication of displeasure or pleasure when stimulated by auditory or mechanical means, even though he may open his eyes if they should happen to be closed. This state of consciousness is also called coma vigil, hypersomnia or parasomnia, a variant of akinetic mutism (39). It is often mistaken for a functional state of stupor. Coma vigil is distinguished from coma in that the patient in coma vigil blinks his eyes with some degree of alertness, shows some purposive reaction to nociceptive stimulation but otherwise displays a total absence of movements, except for those of respiration which are unaltered in rhythm (34).

The syndrome was first described in a patient with an epidermoid cyst of the third ventricle (1). Eleven years later Cairns reviewed his experience, describing one case of traumatic hemorrhage associated with mutism, partial akinesis, negativism, and catatonia, "a state superficially resembling catatonic schizophrenia" (2). In 1952 Jefferson implicated injuries to the brain stem and lesions of the fourth ventricle and aqua-

duct of Sylvius in the etiology (3). This syndrome has also been associated with thrombosis of the basilar artery (4-7), bilateral thalamic hemorrhage and neoplasm (8), colloid cyst of the third ventricle (9-26), craniopharyngioma (33-38), posterior fossa tumors, especially cerebellar (10), bilateral cingulate gyrus lesions (11, 12), pineal tumors (2), head trauma (37), tuberculosis meningitis (13), viral encephalitis of the mesencephalon (14), hydatid cyst of the diencephalo-hypophyseal region (35), glioblastoma of the right frontal lobe (15), infiltrating tumors of the right parietal lobe (15), acute cerebral malaria (16), and illuminating gas poisoning (6). Lesions of the brain stem, however, seem to be the most common cause. A number of lesions has been noted to produce akinetic mute states that simulate, in many respects, catatonic schizophrenia (2, 6, 13-15, 35, 40).

Another case of akinetic mutism following a subarachnoid hemorrhage and ligation of left internal carotid aneurysm and semeiologically similar to catatonic schizophrenia is presented with emphasis on the psychiatric aspects of the syndrome and its possible pathogenesis.

Case Report. In 1959, H.P., a 47-year-old married Negro woman, apparently well until 7 months prior to her admission to the New York State Psychiatric Institute, had the first of 2 episodes of brief unconsciousness associated with subsequent mutism and negativism for several hours, along with denial of illness. Following admission to hospital, she complained of headaches, a stiff neck and lethargy. A second episode occurred 10 days later and was similar to the first except for a brief period of agitation and paranoid ideation. At that time a lumbar puncture yielded a grossly bloody tap with an opening pressure of 140 mm./H₂O. She was transferred to another hospital for neurosurgical evaluation. She calmly accepted the medical recommendations. An aneurysm of the left internal carotid artery arising at the junction of the posterior communicating artery was demonstrated by arteriography, followed by a craniotomy during which ligation of the aneurysm was accomplished. Temporary occlusion of

¹ Dept. of Psychiatry, Columbia Presbyterian Medical Center and New York State Psychiatric Institute, New York, N. Y.

² Present address of Dept. : Neurology and Psychiatry, U. S. Naval School of Aviation Medicine, Pensacola, Fla.

the carotid vessel was maintained for 4 to 6 minutes, during which body temperature was kept at about 27° C.

Postoperatively, the sensorium was clear. The patient recognized members of her family with whom she conversed normally. A complete left third cranial nerve paresis was transiently present. On the third day she became negativistic, agitated and refused to eat. The sensorium was intermittently clouded. On the eighth day the patient began to hallucinate, both auditorily and visually, in a very paranoid manner. Started on chlorpromazine (Thorazine), she became apathetic, withdrawn, depressed, mute, and doubly incontinent. Tube feeding was started, although the patient displayed no actual mechanical defect in swallowing. At times she exhibited intermittent but frankly catatonic signs which were taken by a consultant psychiatrist to be evidence of schizophrenia. She later developed a urinary tract infection and bilateral pneumonitis which subsided with antibiotics. A month after surgery a right hemiparesis with a central facial palsy was evident. The patient continued to be generally mute, withdrawn, and akinetic. Occasionally, she smiled but rarely did she move any part of her body. Hallucinatory behavior became more evident. Chlorpromazine was increased but later stopped, since the hallucinations seemed unaffected by the medication. Fluctuations in the level of consciousness persisted. Occasionally, the patient grimaced. Sometimes she gave the appearance of wanting to speak.

Six weeks postoperatively, a sodium amytal (200 milligrams I.V.) interview was done. The patient was initially responsive, opened her eyes, seemed to be frightened, and gradually became unresponsive and appeared to go asleep. There occurred several bursts of spontaneous speech which was somewhat dysarthric. During the third postoperative month, she was observed to smile on occasion. When seeing her family on Mother's Day, she suddenly exclaimed: "Oh, here's my boys . . . I'll be home as soon as possible." She then drew back into her usual mute state and acted as though her family were not present. Behavior continued to fluctuate. Intermittent urinary and pulmonary infections presented frequent medical problems which necessitated continued hospitalization for 5 months. Before transfer to the psychiatric service, the neurological signs described below were noted. Because of the unusual clinical state, decision was made to transfer the patient to the New York State Psychiatric Institute for further evaluation.

On admission, physical examination revealed

a well-developed but thin, gray-haired Negro woman, staring blankly ahead and lying immobile, unresponsive to any verbal stimuli. The right pupil was one millimeter larger than the left. The fundi were not remarkable. The remainder of the examination of the head, eyes, ears, nose and throat was negative except for a craniotomy scar at the left fronto-temporal area. The lungs were clear to percussion and auscultation. The heart was not enlarged. M_1 was greater than M_2 . A_2 was greater than P_2 . Sinus rhythm was regular. A systolic, harsh, grade II murmur was heard at the apex. The abdomen was flat. No organs or masses were felt. There was a midline suprapubic scar from an old hysterectomy. During the neurological examination the patient occasionally grunted with monosyllables. She sat quietly, regarding all about her with a wide-eyed stare and gave some promise of speech. Eye movements were conjugate. No nystagmus was present. Pupils were equal and responded sluggishly to light. On command she slowly brought her right arm forward to her forehead, but never quite made it. No withdraw movements were made to pin stimuli on the right side of the body below the neck. Stimuli at the neck on the left side caused a delayed movement of the left arm toward the area eventually reaching it. Stimuli on the left hand produced a slow withdraw movement. A more rapid withdraw movement occurred with stimulation of the left foot. There was a marked adductor spasm of the legs, a 30°-40° flexion-contracture of the right knee with a 10° contracture on the left. The deep tendon reflexes were increased more so on the right. There were positive palmo-mental, Hoffmann and Babinski reflexes as well as a snout reflex.

The temperature was 99.4° F.; the pulse was 110 and regular; respirations were 28; blood pressure was 110/70. Complete blood count and urinalysis were negative. An electroencephalogram was diffusely abnormal because of slow activity present over the more anterior portions of both hemispheres, particularly on the left. A comparison with the EEG made several weeks postoperatively showing greater depression of activity over the right anterior temporal area demonstrated now less depression of activity.

It was learned from the husband that several weeks prior to the patient's illness she had complained of insomnia and anorexia and had become quite irritable and suspicious of her husband. He revealed that in the last year she had become alcoholic. Past history indicated that the father was an itinerant minister who

divorced the mother when the patient was aged 10. The patient was given piano lessons at the age of 3, encouraged to be "a concert pianist," but revolted against the mother when she was aged 12. She then experienced an ill-defined psychiatric disorder which resulted in her "having to go away for the summer." In late adolescence she married an older man who divorced her several years later. At the age of 27 she remarried. She had one child with bilaterally absent epiphysal centers in the tibia and fibula. The husband asserted that the patient had felt extremely guilty over their deformed child. For a number of years she had been argumentative, easily annoyed and had had "the habit of staring off into space for long periods" for no apparent reason, although it occurred when she was usually angry. He remarked that the patient had had a very hostile and defiant relationship with her mother, a school teacher, who persistently had encouraged her to do well "for the sake of the family." The patient had been very close to her younger sister, a mute, and had protected the girl against the mother who was quite resentful of this daughter.

There was little change in the patient's clinical condition. Her face remained unexpressive. She did not speak spontaneously except to say, when the ward attendant once spilled her milk: "You are very clumsy." She maintained a sitting or dorsal recumbent position with her eyes staring into empty space, seemingly oblivious of her surroundings. There was no reaction to visual or acoustic stimuli. Although she would indifferently take fluids introduced into her mouth, she made no attempt to chew food. Positions passively imposed on her extremities were maintained for long intervals.

Repeated EEGs showed a pattern of light sleep with slowing which occurred in the form of low to moderate voltage (2-3cps) and (4-7cps) activity. Slower frequencies were most prominent in the more anterior regions, particularly in the left anterior temporal region with some slow spike discharges. Photoc painful and cold stimulation produced no arousal reaction or significant change in the electrical activity.

Several weeks after admission the patient developed a urinary tract infection and was found to have a fecal impaction. She later evidenced signs of a small bowel obstruction and was transferred to the surgical service where an intestinal obstruction with volvulus secondary to old postoperative adhesions was found (17). By the 14th postoperative day the patient's course was stable, and she was trans-

ferred back to the Psychiatric Institute, from which she was later discharged to a hospital for chronic care. It was the general impression that the akinetic mutism was, at least in part, a result of infarction of the area along the left middle cerebral artery with diffuse encephalomalacia.

In 2 months the patient had a recurrence of pneumonitis with congestive heart failure and died. Autopsy revealed diffuse bilateral suppurative pneumonitis with interstitial fibrosis and atelectasis. The heart showed evidence of arteriosclerosis of the coronary vessels, rheumatic mitral insufficiency and hypertrophy of both ventricles. Gross examination of the brain showed severe congestion and edema with the focal left temporal encephalomalacia. There was moderate arteriosclerosis of the cerebral vessels.

DISCUSSION

In the evaluation of the patient's illness, a number of signs that initially suggested schizophrenia were found. She was often inadvertently taken for a catatonic by casual visitors to the ward. The history of an adolescent emotional disorder, the pre-morbid personality pattern of becoming muted and fixed when angry, recent change in her personality with marked irritability, suspiciousness and lability, and a short episode of mutism and negativistic behavior after her first subarachnoid hemorrhage could have been taken as clinical signs in support of such a diagnosis. The reaction to the sodium amytal interview was even interpreted along these lines by a psychiatric consultant. It soon became evident, however, that the patient had sustained diffuse CNS damage and presented phenomenologically the syndrome of akinetic mutism. Diffuse encephalomalacia along the distribution of the left internal carotid artery, distal to the aneurysm, was postulated. At autopsy only focal left temporal encephalomalacia, along with severe generalized congestion and edema, was grossly apparent. Small infarcts and neuronal loss from hypoxia, secondary to the operative procedure, however, may have been present. Microscopic studies were not done.

The semeiotical similarities between akinetic mutism and catatonic schizophrenia have prompted the use of ECT in some instances. One patient, a woman exposed to

illuminating gas for 24 hours, was given a series of ten ECT's because of misinterpretation of her mutism and akinesia(6). Reference is also made to a patient with a bilateral thalamic tumor who, over the course of 2 months, manifested classical signs and symptoms of catatonic schizophrenia without neurological signs(13). A hydatid cyst in the diencephalo-hypophysial region is said to have produced behavioral changes in a patient who initially was excited, aggressive and hallucinating and then suddenly changed, becoming mute, akinetic and posturally catatonic(35). A case of an 11-year-old boy who, after two subarachnoid hemorrhages from a basilar artery aneurysm, ran an unusual clinical course is reported. Initially he was comatose for 2 weeks, then passed into a 3-month phase characterized by mutism and akinesia. The patient then became negativistic, markedly so after 3 months, when he displayed catalepsy, stereotypies, telegraphic speech, and oral-aggressive fantasies, particularly ones of refusal to eat "because his mother would die," and later a sudden and complete loss of his akinetic mute attitude. After passing through a schizophreniform phase, he returned to his previous personality integration. But he continued to have several neurologic signs. This patient was unable to recall the events of the first few months of his illness. After recovery from akinetic mutism, Cairns' patient also had a total amnesia for the illness. This is in sharp contrast to the akinetic schizophrenic patient who, after recovery, has complete memory for the catatonic state and shows, during his illness, no electroencephalographic evidence of drowsiness or absence of an arousal reaction with nociceptive stimuli(27). Another differentiating factor is the sodium amytal interview which produces somewhat different reactions in the schizophrenic and the akinetic mute (24).

Akinetic mutism cannot be attributed to destruction of sensory and motor pathways. It is generally agreed that there is a close relationship between altered consciousness and the reticular activating system(18-20), and that akinetic mutism is a result of partial damage to the reticular activating system or interruption between the reticular activating system and its cortical and sub-

cortical connections(21-23). The inclusion of such varied nosological conditions under the rubric of akinetic mutism has been questioned on the basis that only cases showing interruption of the ascending activating system should be included. It is thought that enlarging the syndrome might "impair the purity of the notion and efface its primary meaning"(13). Such pathologic specificity is unwarranted at this time, since it is often difficult to implicate directly the reticular activating system with such varied neuropathological lesions resulting in akinetic mutism.

What is the role of the pre-morbid personality in the development of akinetic mutism? Is there a selective and motivated part of the behavior of the akinetic mute? The reported patient had employed silence, withdrawal and avoidance as a mode of response to stress. When angered she would stare off into space for long intervals and was bilaterally unattentive(24). How she learned this motive adaptation is not known, except that the younger sister, with whom she was very close, was a mute. Identification with this sister may have been important in the selection of this defense. Prior to the illness, she had turned to alcohol in avoidance of a marital problem. An exaggeration of her well-established tendency to suffer illness in silence and to express resentment by retreat to isolation was then more prominent.

The similarities between schizophrenia and akinetic mutism have stimulated speculation on the pathogenesis of catatonia. Referring to Pavlov's view of catatonia as a state of chronic hypnosis, Steriade, *et al.*, in seeking a pathogenesis of schizophrenia invoke partial interruption of the medial inferior reticular activating system, resulting in a de-afferentation of the cortex(13, 31). Studies on sensory deprivation are used in support of such speculation. Limitation in sensory input is thought to result in an accumulation of epinephrine and norepinephrine with increased sensitivity of the rostral midbrain tegmentum and sympathetic nervous system(25). Interconnections between the cortex and reticular formation have been established. Ideation can stimulate the descending and the ascending reticular activating system, thus producing a

state of activity in the cortex. Corticofugal influence, therefore, can serve as arousal, alerting, or retentive devices in the reticular activating system with reflected changes to the cortex(28). Experimental evidence indicates that hallucinations and possibly delusions can be produced by sensory deprivation(29), and are often schizophrenic in character(30). Dissociation between the cognitive and volitional facets of synthetic ego functions in akinetic mute states is not dissimilar to the dissociation seen in psychoses and dreams(36).

But even with recent multi-factorial studies(15) of akinetic mutism and its exfoliations its pathogenesis, particularly in man, remains obscure. Nevertheless, it is helpful to colligate clinical and experimental data.

NEGROES IN PSYCHOTHERAPY¹

HAROLD ROSEN, M.D., AND JEROME D. FRANK, M.D.²

Until less than a decade ago, almost the only psychiatric treatment available to the Negro was through public clinics and state mental hospitals. This is no longer the case. Two trends are now making private psychiatric care progressively more available to Negroes. One is the increasing number of psychiatrists including, we are glad to note, Negroes. The other is the rapidly rising socio-economic level of the Negro and the crumbling of interracial barriers(1, 5). Even in a border State such as Maryland most private psychiatrists now treat Negroes, and all but one of the major private hospitals accept them on a non-segregated basis,³ although 10 years ago none admitted Negroes. There has in addition been a concomitant expansion and improvement of state hospital and clinic care and a widening range of available forms of therapy, both group and individual. It therefore seems appropriate to study the relationship between white therapist and Negro patient, since this affects the course of therapy.

This relationship is determined by the personal characteristics of the therapist and patient, and by the cultural attitudes of Negro and white towards each other. The therapist must be aware that such factors exist and be able to focus on them when it seems therapeutically indicated, but without being so concerned with them as to overlook more strictly personal issues.

Negroes, when seen in psychiatric consultation, present the same general personality and treatment problems(8) and fall into the same general diagnostic categories(9) as do whites of approximately the same class status(6). Similarities between white and Negro are greater than differences(4).

The latter are nevertheless present(14) and must be given serious consideration. Negroes have the adjustment problems of all underprivileged minority groups—we have seen almost identical phenomena in Irish, Italians, Poles, Jews (and even among "Georgia crackers" and so-called poor whites)—but in Negroes the problems are apt to be more intense and pervasive, because they wear with the color of their skin an undisguisable sign of their minority group status(3).

The present, rapidly changing status of the Negro is an additional source of stress. The 1954 Supreme Court decision(1, 2), with the pressures for de-segregation to which it has given rise, is making itself felt with increasing sharpness in political, economic, religious, educational, and cultural areas. The Negro is fighting to win recognition, in both Southern and border States, as a mature human being(3a). As, with the passage of time, his social, economic, and class status improves(5), special problems will be posed in the fields of individual and social psychiatry(3a).

Neither can be considered apart from the other, since there is an inter-reaction between the two. When our society becomes healthier in this respect and, so we hope, no longer emotionally traumatizes the Negro in his formative years, the reactive guilt of the white—and what this means to him emotionally—will disappear. But at present the paranoid insecurity and guilt not only of the bigot but even of those without conscious race prejudice may at times be intensified as the problem, during the course of its ultimate solution and dis-solution, at first comes into sharper and sharper focus.

Few of us are entirely free from race prejudice; with some, this is overt; with others it may be below the level of conscious awareness. It may express itself in overt activity; it may—more happily—never be allowed such expression.

Certain aspects of the problem become highlighted in the psychotherapeutic relationship. The white therapist, vis à vis his

¹ Based on a preliminary report presented December 28, 1956, to the fourth annual congress, the Inter-American Society of Psychology, University of Puerto Rico (San Juan, Puerto Rico).

² The Johns Hopkins University School of Medicine.

³ The State Hospital System does not. Negroes requiring psychiatric hospitalization are admitted to the Crownsville State Hospital; while white patients go to the other State Hospitals.

Negro patient, need seldom contend with *conscious* prejudice in himself, because if this were present he would not have accepted the patient for treatment. He must, however, be alert to the possibility of *unconscious* prejudice. This may manifest itself either directly or through reaction formation. He may, for example, subtly reject Negro patients so that they stop coming to see him. Or conversely, especially if he is a member of a minority group himself, he may over-identify with them and lean over backwards by, for example, scheduling certain patients for extensive or intensive treatment when neither is indicated.

The more pronounced the unconscious insecurities and guilt of the white psychotherapist in this area are, the more ineffective his treatment contact with these patients must necessarily be. As his own guilt begins to disappear, he will find himself able to treat Negro patients more effectively instead of, unwittingly and for personality reasons of his own, traumatizing them still further.

The Negro, as a member of a minority group, inevitably brings certain attitudes into treatment; three—resentful anxiety, distrust, and “self-hatred”—require comment. Resentment and anxiety are produced by past experiences of discrimination.⁴ Negroes never know how they will be received by whites in new situations. Almost all have suffered unexpected humiliating rebuffs. Moreover, at least in many Southern and border States, they are even now still denied equal protection of the law and as a result not infrequently undergo genuinely threatening experiences. One colored physician, for instance, while driving with a light-

skinned companion in a Southern State, was arrested and threatened with jail because his companion's protestations that she was colored were disbelieved. There were veiled hints that, if this girl would permit sexual advances by the officer, the charge would be dropped. If freedom from fear is desirable for any citizen, as Tomkins has stated, it must be desirable for all citizens (6a).

Because of experiences like this, Negroes characteristically develop distrust of all whites (the second of the three attitudes so frequently seen during treatment), and unwillingness to reveal weakness to them. This, incidentally, is a greater obstacle in group than in individual therapy (12). The Negro's distrust of white patients in a therapy group is greater than his distrust of the white psychotherapist whose professional status tends to counteract this attitude.

The third commonly found culturally-induced attitude, “self-hatred,” has been noted in all underprivileged minority groups. Whiteness represents full personal dignity with complete participation in American society. The Negro, therefore, who is most nearly white in appearance, class and educational status, and attitude has tended to be embarrassed by and to look down upon Negroes who more closely resemble the white stereotype of the Negro (15), while the Negro who is more closely identified with his group resents the attitudes of the more “assimilated” Negro, and at the same time may secretly envy him. Such attitudes connected with “self-hatred” are particularly difficult to reveal in the presence of whites, but eventually do appear if therapy is sufficiently prolonged.

These points may be illustrated by an example from a mixed white and Negro psychotherapy group. Such groups present particular problems for therapy arising out of these culturally induced attitudes; they also throw such attitudes into relief. This example highlights the protective reticence of Negroes in the presence of whites, contains a hint of the “self-hatred” phenomenon, and indicates this distrust of whites. This experience occurred in a border state (Maryland) where such attitudes are prominent.

⁴ There, for instance, have been over 3700 arrests since February 1, 1960, when 4 first-year students at an all-Negro college in Greensboro, North Carolina, started the sit-in by refusing to leave a segregated lunch counter which had denied them service, but remained seated reading their Bibles and studying their texts. On the bright side, over 5000 eating facilities have now desegregated as a result of sit-ins, “Freedom Rides,” etc., since. In the past year-and-a-half such demonstrations in the Washington suburban area have attracted large numbers, including five U. S. Congressmen. The psychiatric implications of this are discussed in detail in a very thought-provoking article by Fishman and Solomon (3a).

Through an unusual concatenation of circumstances a mixed group, ordinarily conducted by a white therapist, had one meeting in which two members only were present, both Negroes; this time the therapist, likewise, was a Negro. One of the patients, Mrs. B., a schoolteacher, explained, "It will be much easier to talk since we are all the same," and then discussed what she felt to be her husband's irresponsibility, something which she could not bring up when whites were present because, in her opinion, this coincided with the whites' stereotype of the Negro male. Later she mentioned her annoyance, which she had never previously expressed in the group, because Mrs. G., a colored housewife of clearly inferior social and educational status, at an earlier meeting had said something critical about schoolteachers. These reciprocal attitudes, manifested by Mrs. G. and Mrs. B., could be interpreted as representing an example of "self-hatred" expressed in an oblique way. At the end of the meeting she told of her inability to trust a certain white social worker because, although this worker was friendly to Mrs. B., she had made remarks which Mrs. B. interpreted as uncomplimentary to Negroes in general. The therapist felt that Mrs. B. was referring also to the therapy group situation but this did not become explicit, nor did it seem at this particular time as though it should be raised for therapeutic discussion.

Racial discrimination may contribute to the psychopathology of the individual Negro patient in a variety of ways. Specific incidents occasionally serve as precipitating factors in the onset of severe neurotic or psychotic symptoms. Racist discrimination may help determine the content of grandiose or persecutory delusions(7). It may serve as a chronic precipitant for repetitious anxiety-producing situations which, over a lifetime, predispose the individual concerned to see racial (or religious) discrimination where none exists. It may channelize the antisocial behavior of individuals with severe personality disorders and so-called character neuroses(11). Some may use it as an alibi for their own inadequacies. By making it possible for exploited individuals to vent aggression against members of their own or other minority (or majority) groups, it may constitute a defense against the onset of neurotic or even psychotic symptomatology.

In any case, patients concerned continue to be chronically psychogenically traumatized. So, frequently, are all with whom they come in contact.

Some specific implications of these points for the psychotherapeutic relationship may now be considered. First, the distrust which the Negro often brings to the white therapist may manifest itself in obscure ways which lead either therapist or patient to misinterpret what is going on. For example, patients without motivation for treatment are told they must learn how to live with their symptoms. If the patient be a Negro, he may attribute this to anti-Negro prejudice in the psychiatrist. This poses special problems for the therapist. Leaning over backwards and scheduling such patients for treatment is not only a waste of what otherwise could be productive psychiatric time, but is as much evidence of underlying race prejudice as refusal to accept Negro patients.

Similarly, the Negro for whom psychiatric hospitalization seems advisable, or members of his family, may feel that if he were white he would be accepted for treatment on an office basis. Four of our private patients, for instance, were convinced that the recommendation for hospitalization was a thinly disguised means of rejecting them. If the white psychiatrist does not realize this and take the time to correct it, the recommendation for hospitalization may not be accepted."

If the patient accepts hospitalization, he may find that since no private psychiatric beds at the time are available he must be placed on a waiting list. This situation arises even in the total absence of discriminatory policies, but the Negro will almost certainly interpret it as race prejudice on the part of the referring psychiatrist or hospital administration. This, therefore, also must be discussed during the consultation sessions.

Membership in a minority group tends to lead to certain habitual ways of relating initially to a member of the majority group. The white therapist who sees Negro patients needs to be aware of these. Such patients are still apt to show either sullen reserve, or loquacious and obsequious over-

affability.⁵ If the therapist permits himself to be antagonized by the former, or to be deceived into accepting the latter as expressing his patient's actual feelings, the development of a good psychotherapeutic relationship will be handicapped. Furthermore, many Negroes, especially of lower class status, tend to defend themselves against anticipated demands from the white by assuming an exaggerated air of indifference and stupidity.⁵ The white psychiatrist may be misled by this into making an unwarranted diagnosis of mental deficiency or even of simple schizophrenia; yet the same patient may show normal responsiveness and intelligence when interviewed by a colored psychiatrist.⁶

The Negro's position as a member of a minority group subjects him to experiences which differ from those of the white of corresponding socio-economic status, and the therapist must evaluate the patient's history with this in mind. Intermittent school attendance or frequent change of job may indicate not emotional instability but the effort to survive. Nor need a jail sentence have the same implications for a Negro as for a white patient (14). Freedom from psychopathic traits and a high degree of morality do not necessarily protect the Negro from arrest on suspicion in many communities.

Traumatic experiences which the Negro patient has suffered, as a direct or indirect result of discrimination, may become intertwined with his personal neurotic difficulties. Various authorities comment on the frequency in the matriarchal home, so characteristic of the American Negro, of a harsh and unstable father (13); others stress the large number of broken homes among their patients, the death of one or both parents, the desertion of the father, and the strong emotional attachment to a frustrated and insecure mother (4).

The discrimination and segregation, which the patient suffers from a rejecting,

frustrating social order, frequently revivifies emotions experienced during infancy and early childhood. Both aspects of the problem must be worked through with some patients if even symptomatic relief is to be obtained.

While an understanding discussion of problems of prejudice may be of therapeutic value, this can readily be utilized, by therapist as well as by patient, for arm-chair philosophizing which prevents a good treatment relationship from developing. Unless he is aware of his own underlying problems in this area, the psychiatrist may use such a discussion, while apparently treating his patient, in actuality to reject him.

Although the psychiatrist can do little to change the real situation, he can discuss its emotional concomitants and how these bear on the patient's present emotional maladjustment. If treatment is to be successful, no such discussion, however, can remain on an intellectual basis.

This can be illustrated with the sharpness of caricature by a consideration of patients under psychiatric treatment on hypnotic levels. If the problem of race prejudice comes up during early sessions, especially during the first two or three, race-consciousness may be expressed in the patient's resentment against the white man as such, and especially against his therapist. This may take the form, if the therapist be Jewish, of anti-Semitic remarks (10). If it occurs later during treatment, the patient almost invariably ties it up with childhood experiences toward an authority figure.

A normal school student, while being hypnotized, felt what she characterized as an irresistible urge to punch one of us (H.R.) in the jaw. She tried to keep from doing so. As her fist shot out, barely missing his face (which he had inclined somewhat to the side), she was regressed by direct hypnotic suggestion to that other time when, so she was told, she had felt exactly the same way. She immediately became a 5-year old, had just swallowed the food which her father was forcing down her throat, and wanted to kill him (10). This was handled in the same way as it would have been with a white patient.

In conclusion, two points may be stressed:

1. Most Negro patients whom we have

⁵ This seems to be in a process of change. During the past year-and-a-half, these attitudes have been rejected, at least in our clinical experience, by patients seen *privately* in consultation or for brief, goal-limited psychotherapy, who were under 23 years of age.

⁶ We are indebted to the late Dr. Ethel Nixon for demonstrating this point to us with several psychiatric clinic patients.

seen in psychiatric consultation, evaluation or treatment are, as a result of the experiences to which they were subjected because of the color of their skin, both race-conscious and resentful of the imperfections of our democracy. If therapy be attempted, whether privately or in a clinic, these feelings must be brought out into the open and collaboratively discussed. The blind spots of the therapist are of prime importance in determining the outcome of such discussions.

2. The patient is applying for psychiatric treatment. He has symptoms that are incapacitating or invalidating him. It is treatment for these—and not an intellectual discussion of race prejudice—that he needs. The personal problems of each patient are unique regardless of the color of his skin, and each must be treated as an individual.

If the white therapist bears these points in mind, his Negro patients, both private and clinic, whether individually or in groups, can and do make gratifying, very steady progress.

CLINICAL NOTES

(The Clinical Notes report the findings of the authors and do not necessarily represent the opinion of the Journal.)

PROPIOMAZINE FOR CONTROL OF INSOMNIA IN NERVOUS DISORDERS

ADAM J. KRAKOWSKI, M.D.¹

Insomnia, a frequent concomitant of nervous disorders, has been treated in innumerable ways, with varying success. It is generally agreed that heavy dosage of standard hypnotics should be avoided; an adequate dose of an ataraxic with strong hypnotic properties may be more desirable. This is a preliminary report of oral medication with propiomazine (Largon) for insomnia in patients under treatment for a variety of nervous disturbances in two general hospitals and a psychiatric office practice.

This compound resembles promethazine (Phenergan) in acute toxicity and pharmacological properties(1). In preanesthetic and predelivery use the compound has been injected intravenously or intramuscularly, alone or in combination with other agents, with onset of effect in 6 to 10 minutes, and duration of 3 to 4 hours(2-5).

METHOD

Propiomazine was administered orally, at random, to 17 men and 39 women, with an average age of 45. The diagnoses included psychotic depression, 33; neurosis, 15; schizophrenia, 5; and simple insomnia (wakefulness only), 4. Two were pregnant; two men and 1 woman were alcoholics; for 7 patients barbiturate and nonbarbiturate hypnotics had been tried unsuccessfully. *Dose*: Four patients with simple insomnia received 40 mg. propiomazine only, at bedtime. The others were given ataractic or antidepressant medication, or both, to control the main target symptoms: promazine, with or without meprobamate, 17; chlor-diazepoxide, 9; hydroxyzine pamoate, 3; prochlorperazine or chlorpromazine, 3;

thioridazine, 1; 27 received imipramine, chlorprothixene or nialamide, singly or in combination. When the principal medication failed to induce sleep, 40 mg. propiomazine was added, at night, 2 hours after the last dose of the other agents, and was continued 1 to 10 weeks. If no sleep occurred in 3 consecutive nights, the same dose was repeated up to 3 times a night, and occasionally was increased to 60 mg. 3 times a night. If unsuccessful in 1 week of consecutive nightly trials, treatment was stopped. Most were already under laboratory control; no special studies were done. Results were considered excellent if sleep occurred in $\frac{1}{2}$ hour, lasted 6 hours or more, and no side effects were present on awakening; good, if sleep occurred in less than 1 hour and lasted, perhaps with intermittent waking, at least 4 hours, with no side effects. Satisfactory response was obtained in 77%: excellent in 39%; good in 38%; no sleep occurred in 23%. The result was excellent in simple insomnia; there were no failures among the schizophrenics. In depressed psychotics excellent, good, and poor results occurred in about equal numbers. Of the neurotics, 80% had good results; 20%, poor. Of those who had not slept under barbiturate or nonbarbiturate sedation, 3 had an excellent, 2 a good, and 2 no result with propiomazine. Side effects occurred in 5 patients (9%), all depressive psychotics, when the dosage was increased. Three of them showed greater agitation and daytime drowsiness when the dose was raised; 4 had headache on awakening, 2 complained of dryness of mouth, and 1 of nausea. These symptoms disappeared on withdrawal of the compound. No evidence of toxicity, photosensitization or other allergic reaction developed.

¹ Champlain Valley and Physicians' Hospitals, Plattsburg, N. Y.

SUMMARY

Fifty-two psychiatric patients and 4 with severe insomnia only received propiomazine orally as a hypnotic. 1. Forty milligrams proved the most satisfactory dose; smaller amounts were relatively ineffective; larger doses did not increase the hypnotic response. 2. Seventy-seven percent exhibited a good to excellent result. 3. No toxic effects or severe side reactions were observed. Propiomazine is an effective hypnotic, comparable to the new synthetic sedative agents. Further studies are recommended.

PROCYCLIDINE AND BENZTROPINE METHANESULFONATE COMPARED IN DRUG INDUCED EXTRAPYRAMIDAL REACTIONS

ROBIE T. CHILDERS, JR., M.D.^{1, 2}

Since the introduction of the phenothiazines there has been an increasing recognition of the troublesome and at times incapacitating extrapyramidal symptoms that are so frequently encountered. In a thorough discussion of extrapyramidal symptoms Ayd(1) points out that females are more prone to development of these symptoms and the type of symptoms encountered varies with the drug used. "Dyskinesia occurred the earliest, akathisia next, and parkinsonism last in the course of treatment."

The incidence of extrapyramidal symptoms varies widely. Ayd lists 63% incidence in females. In a report(2) published earlier we encountered 22 extrapyramidal symptoms in 25 patients treated with 40 mg. trifluoperazine daily and 12 such symptoms in 22 patients treated with a daily dosage of 1000 mg. chlorpromazine. It is generally agreed that most antiparkinsonian drugs bring rapid improvement in the majority of extrapyramidal symptoms. The purpose of this study was to compare the improvement rate with two of the commonly used antiparkinsonian drugs and to determine the incidence of side effects of said drugs.

Female patients on acute intensive treat-

ment were divided at random into two groups of 35 each. Average age 39. Thirty-one were on chlorpromazine 800 mg. daily, 20 were on trifluoperazine 40 mg. daily, and 19 were on fluphenazine 20 mg. daily.

Patients were seen every other day and the type and severity of extrapyramidal symptoms were noted (see Table 1). Group A received benztropine methanesulfonate (Cogentin) starting at 2 mg. daily and increasing by 2 mg. every other day until symptoms were controlled or a 6 mg. daily dosage was reached. Group B received procyclidine (Kemadrin) starting at 2.5 mg. daily and increasing by 2.5 mg. every other day until a dosage of 7.5 mg. was reached or symptoms had been controlled. Side effects were noted for each drug (see Table 2).

Side Effects of Benztrapine Methanesulfonate
and Procyclidine

DOSAGE BENZTRAPINE METHANESULFONATE	SIDE EFFECTS	
	BLURRED VISION	DRY MOUTH
2 mg.	3	1
4 mg.	3	2
6 mg.	3	5
PROCYCLIDINE 7.5 mg.	2	0

SUMMARY

Seventy patients on acute intensive treatment with chlorpromazine, trifluoperazine, and fluphenazine were placed at random in two groups. Group A treated with benz-

trapine methanesulfonate had 40 extrapyramidal symptoms of which 35 improved. Blurred vision or dry mouth developed in 17 instances. Group B treated with procyclidine had 40 extrapyramidal symptoms of which 39 improved with the development of only one side effect—blurred vision—in two patients. On the basis of this study it appears that procyclidine was the most effective drug in alleviating extrapyramidal symptoms. The number of side effects developing with procyclidine were at a minimum.

IMPRESSIONS OF THE POSSIBLE EFFECTS OF A NEW TRANQUILIZER, HYDROXYPHENAMATE ¹

JOHN MEYER, M.D., AND MARY BUSWELL, B.S.N.²

The title of this report is modest, and deliberately so. The writers have long believed that studies of psychiatric drugs do *not* prove their ability to "cure" or "improve" patients, and should not be reported as such. At St. Jude's our attempts to reproduce the favorable results reported in the literature have almost always led us to the conclusion that nearly all psychiatric drugs are practically worthless. The factors in every psychiatric case are so many and varied, as is well known, that the honest research man can do only what has been done here :

1. To give a drug to a group of mentally ill persons, having evaluated (in the crude fashion to which we are still limited) the "type" of illness, its symptoms and its severity in each case.

2. To observe and to question the subjects during and after treatment, noting what changes (for better or for worse) have taken place.

3. To conclude, in all humility, that the drug *may* have been responsible for some of the changes ; and to report, percentage-wise, these changes in the subjects.

During the past 6 months a new tranquilizer, hydroxyphenamate (Listica), was given in various doses (usually 1 tablet, 200 mg., 3 or 4 times a day, but in a range from 1 to 7 tablets daily) to a group of 32 mentally sick persons. Duration of treatment varied from 2 weeks to 6 months (average, 1 month).

Diagnostic "labels" were ascribed to the subjects ; but, since psychiatric diagnosis continues to be based on symptoms and is highly inadequate, the subjects were divided simply into "neurotic," "psychotic," *etc.* Statistics follow :

"*Diagnosis*" : Neurotic—25 ; psychotic—5 ; sociopathic—1 ; schizoid—1.

Sex : Male—10 ; female—22.

Age : Teens—1 ; 20's—13 ; 30's—10 ; 40's—2 ; 50's—3 ; 60's—3.

Improvement in symptoms : "Excellent"—21 (66%) ; "good"—6 (19%) ; "fair"—4 (12%) ; "poor"—1 (3%).

¹ Hydroxyphenamate was supplied by Armour Pharmaceutical Co., Chicago, Ill.

² Director and Assistant, St. Jude's Medical Research Center & Clinic, Cedar Rapids, Iowa.

New symptoms reported (possible side effects of the drug): Persistent drowsiness, mild to moderate, in 7 (22%); reduced by cutting the frequency of dosage in 5 of these 7. Other "side effects"—apparently none.

IMPRESSIONS

1. Hydroxyphenamate seems to be a potent tranquilizer, varying degrees of improvement occurring in 97% of 32 mentally ill subjects during its use, and usually persisting after it was discontinued.

2. Hydroxyphenamate seems to be of value as an aid to sleep, perhaps through the reduction of anxiety: nearly all the

subjects reported improved sleep while taking the drug.

3. Drowsiness may be a side effect (22%), but was usually reduced when dosage was cut.

4. No other side effects were reported. The drug seems to be unusually free of side effects.

5. From various experiences, the impression is left that hydroxyphenamate may possibly be helpful in combatting alcoholism, overeating, tension headaches, excessive smoking. Its effect on depression seems uneven: when agitation is a large part of the depression, there is improvement. Further research in these areas is indicated.

HISTAMINE-INDUCED VANIL-MANDELIC-ACIDURIA IN THE SCHIZOPHRENIC AND THE NON-SCHIZOPHRENIC PSYCHIATRIC PATIENT¹

PAUL KOCH, Ph.D., PIERRE LEFEBVRE, M.D.,
ROGER LEMIEUX, M.D., AND CAMILLE LAURIN, M.D.²

This study is part of a research(1-3) undertaken to establish, if possible, simple biochemical differences between schizophrenic and non-schizophrenic psychiatric patients.

Hoffer, *et al.*(4), have put forward the hypothesis that schizophrenic symptoms may be the result of adrenochrome, a toxic metabolite of the catecholamines. No increase of adrenochrome, however, has ever been demonstrated in the schizophrenic(5). Neither does Bergman(6) find any difference in the urinary excretion of catecholamines between the schizophrenic and the non-schizophrenic. Armstrong, *et al.*(7), have shown that urine contains a final metabolite of the catecholamines the 3-methoxy-4-mandelic acid (VMA). This substance is present in much higher concentrations than the parent substances and can be determined much more easily. Mann, *et al.*(8), as well as Pind, *et al.*(9), have determined VMA in the schizophrenic urine

without finding any difference from the normal urine. In accordance with previous hypotheses(1-3) we thought that inducing higher levels of catecholamines would perhaps result in a measurable difference of VMA between schizophrenics and non-schizophrenics. Haigh, *et al.*(10), as well as Rouleau, *et al.*(11), have observed a greatly increased tolerance in schizophrenics towards histamine. We thought it expedient to try histamine as a stressor for VMA-uria induction.

MATERIALS AND METHODS

Thirty-two schizophrenics, males and females, were compared to a similar group of other psychiatric patients.

On the first day all medication was suspended at noon and was not resumed until after the end of the experiment. Each subject received, however, 200 mg. chloralhydrate upon retiring to insure sleep. Fasting was enforced each day after supper, lasting until noon of the following day.

On the second day the patient was instructed to urinate at 8:30 a.m. This urine was discarded. An injection was given of

¹ This study is supported by the Canadian Ministry of Health and Welfare.

² Albert Prévost Institute, 6555 West Gouin Blvd., Montreal, Canada.

We wish to thank Miss Fernande Bastien for her excellent technical assistance.

1 ml. 1:1000 histamine phosphate (BDH., as used in gastric analysis) or an injection of saline (placebo). All urine was collected for a period of 210 minutes (until noon). On the 3rd day the same routine was followed in such a way that at the end of the experiment half of the patients had received the placebo before histamine and vice versa. The acidified urine of the first day was refrigerated until the next day, when the second sample became available. Both were assayed together for VMA according to the method of Sunderman(12). Since mictions were lost, results were calculated as milligrams VMA per gram creatinine rather than per volume. Only pairs of samples showing a similar concentration of creatinine were retained.

RESULTS

In order to minimize the great variations of VMA within each group as well as facilitate the presentation of the results, the differences of VMA between placebo- and histamine-induction (delta VMA) were employed rather than actual concentrations.

TABLE 1

	NUMBER	AGE	Δ	VMA	VARIANCE	SIGNIFICANCE
Schizophren. men	27					
	22	(21-39)		2.35	9.13	0.01%
Non-schizophren. men	33					
	19	(21-51)		-1.02	6.54	20%
Schizophren. women	29.8					
	10	(22-44)		-1.21	14.9	
Non-schizophren. women	33					
	14	(18-50)		-3.44	9.77	

DISCUSSION AND CONCLUSION

There is a highly significant increase of

VMA excretion in the schizophrenic male subsequent to histamine-injection.

Schizophrenic women would appear more tolerant to histamine. Non-schizophrenic women on the other hand may even show a depression of urinary VMA after histamine (at a level of significance of 8%).

SUMMARY

Intramuscular histamine can be used to confirm a diagnosis of schizophrenia in the young schizophrenic male. It will increase his urinary excretion of vanil-mandelic acid significantly. Histamine induced vanil-mandelic-aciduria will neither occur in the non-schizophrenic psychiatric male patient nor in any psychiatric woman patient, schizophrenic or not.

THE EFFECTS OF G-33040 IN DEPRESSIVE STATES: A MULTI-BLIND STUDY

H. AZIMA, M.D., A. SILVER, M.D., AND D. ARTHURS, R.N.¹

The purpose of the present note is to report on a control study of a new drug, G-33040 (Ensidon).² It has an iminostilben

nucleus, with an attached piperazine side chain. Its chemical formula is: 4-[3-(5H-Dibenz [b,f] azepin-5-yl)propyl]-1-piperazine ethanol dihydrochloride. In laboratory studies it exercises a sedative action on the autonomic nervous system, has an anti-

¹ McGill University, Dept. of Psychiatry, Montreal, Canada.

² Manufactured by Geigy Pharmaceuticals.

emetic, anti-histaminic, anti-serotonin action; and, like imipramine, inhibits the potentiating effect of reserpine(1).

The setting where Ensidon was tested is called "multi-blind" and has been previously described(2, 3). In this setting, three groups of patients were compared each consisting of 30 depressed patients (20 neurotic and 10 psychotic depressions in each group). One group received Ensidon and the other two inert and potent placebo (phenobarbital) respectively. The dosage regime was that of "gradual increase." Ensidon was administered with an average daily dosage of 100 mgm. (maximum 300, minimum 25), for an average period of 25 days (maximum 240, minimum 14 days). The potent placebo was administered with an average daily dose of 50 mgm. of phenobarbital and both placebos were given for an average of 21 days.

The vital statistics of the three groups were relatively similar: 9 males and 21 females in the drug group with an average age of 45; and 13 males and 17 females in the inert placebo group with an average age of 40 (potent placebo as well).

Of 30 patients in the drug group, 14 patients (46.6%) showed significant improvement (13 moderate, 1 marked). In potent placebo group, 6 patients (20%) showed moderate improvement and in inert placebo group, 5 patients (16.6%) showed significant improvement (4 moderate and 1 marked). Divided into diagnostic groups, in the drug group 11 neurotic and 3 psychotic depressions showed significant improvement; in the potent placebo group, 3 neurotic and 3 psychotic; and in the inert placebo group, 3 neurotic and 2 psychotic depressions manifested a significant improvement. It should be noted that the onset of the therapeutic response varied between patients, but on the average it was within 4-5 days.

Statistical analysis of the data (using X^2 technique) revealed the following results: Comparison of the drug with inert placebo in 30 patients was significant beyond 0.05 level ($X^2=4.93$, $0.05>P>0.02$); comparison of the drug with the potent placebo in 30 patients reached just the level of significance ($X^2=3.89$, $P=0.05$); comparison of the drug with both potent and inert placebo in 20 neurotic depressions was significant beyond 0.05 level ($X^2=5.38$, $0.5>P>0.02$).

Side effects were minimal and consisted of drowsiness in 10 patients, headache in 5, perspiration in 2 and dizziness in one. Drowsiness appeared in different degrees in all patients in the first week, and appeared to be due to sedation action of Ensidon which could be useful as a sleep regulating factor. Laboratory test data (alkaline phosphatase, white count and differential and urinalysis once a week) remained within normal limits.

CONCLUSIONS

From the data obtained from the present sample, the following conclusions may be drawn: 1) considering the rigorously controlled setting in which the drug was evaluated, Ensidon seems to be an adequately potent antidepressant substance reaching the statistical significance beyond 0.05 level; 2) the indication par excellence is that Ensidon seems to be effective in neurotic depressive states clinically and statistically and there is a relative lack of side effects and the sedative properties of this drug adds further to its suitability for ambulatory patients.

EXPERIENCES WITH CHLORPROTHIXENE IN A STATE HOSPITAL

PETER B. HAGOPIAN, M.D., AND RUTH M. CROSSFIELD, M.D.¹

¹ Respectively, Medical Superintendent, Director of Psychiatry, Danvers State Hospital, Hathorne, Mass.

Chlorprothixene (Taractan), a new potent psychopharmacologic agent, has been shown in clinical trials to have a pro-

found tranquilizing effect on patients with both psychotic and psychoneurotic disturbances, its activity primarily being directed toward states of agitation. Structurally it is similar to chlorpromazine, usually employed for tranquilizing activity, and imipramine, in general use as an antidepressant.

Chlorprothixene has been used at Danvers State Hospital for 3 years and during that time over 400 patients have been treated with this medication. This present study concerns a series of 168 patients still under active therapy either in the hospital or at home, under supervision. The criteria used for placing patients on this drug was recognition of hyperactivity, agitation or insomnia. Chlorprothixene proved to be the agent most likely to restore the patient rapidly to a quiescent and manageable state when it was given alone or in conjunction with other antipsychotic drugs. Because of our comparatively large number of admissions (1400 in 1961) and the heterogeneous nature of complaints, virtually every type of patient, many with associated medical disorders, was treated with chlorprothixene. The majority of patients fell within the 41- to 60-year age group, although a very considerable number were in the 61- to 80-year bracket. The span of treatment was from 1 month to 3 years with over one-third of the patients being under continuous therapy with chlorprothixene for 9 to 18 months. Only female patients were used in this study, primarily because of the distribution of work in the hospital.

The majority of patients received an initial dosage of 100 mg. daily. The lowest initial dosage was 15 mg., and the highest was 900 mg. Once the state of agitation was controlled, the patients were placed on maintenance therapy, the range of which varied from 15 to 800 mg. daily, the majority being maintained on 100 or 150 mg. as the daily optimum dosage.

Many of these cases were long-standing and had not shown significant improvement with other ataractic drugs. With chlorprothixene a 74% marked or moderate improvement was noted. The patients who showed marked and moderate improvement are as follows: 17 or 89% of 19 depressed patients; 35 or 70% of 53 schizophrenics;

15 or 60% of those 25 patients with chronic brain syndrome. It is our experience that this has been an extremely useful drug in our type of service for the management of the above-mentioned cases.

Side Effects. Side reactions following the use of chlorprothixene were limited or not enough to warrant discontinuance of therapy except in 1 case. Drowsiness was the commonest. Parkinsonism was observed in 2 patients; 1 patient developed a very mild form at a dosage of 150 mg. daily but had been on the drug for 8 months before this developed and therefore it was felt unlikely that the mild parkinsonism noted bore any relationship to the therapy. Changes in liver function were not noted nor were there any cases of jaundice. Pre- and intra- or post-therapy hematology was performed in 45 patients, 25%, and no abnormalities were found.

In this series mild hypotension (90/60 Hg) was observed in only 5 patients, 30%. One of the patient's records revealed that this same blood pressure reading was encountered with every similar medication given to her previously and therefore therapy was discontinued in her case. Side effects such as excitement, dryness of mucous membranes, ankle edema, stupor or depressive activity were not noted.

For the patient with agitation, hyperactivity and tension we have found chlorprothixene the drug of choice. It has been almost universally successful in depressions with agitation but ineffective in depressions without agitation. In schizophrenia, chlorprothixene has been most effective when used in conjunction with phenothiazines where psychomotor agitation was involved and in the arteriosclerotic and senile patients where these symptoms frequently present problems.

The acute withdrawal symptoms of alcoholism responded with conspicuous success to immediate and adequate treatment with chlorprothixene.

Of particular note has been the ability, unlike the phenothiazines, to control agitation in the patient with an underlying depression and at the same time not deepen the degree of depression.

For the average hospitalized patient, the starting dose was 150 mg. a day, except in

debilitated or elderly patients in which case 75 mg. per day was given. Dosage changes were not considered until at least one week

of therapy was completed, except in the aged group where many were immediately dropped because of hypotensive reaction.

CHLORPROTHIXENE IN THE TREATMENT OF PSYCHOTIC PATIENTS

JOSEPH A. BARSA, M.D., AND JOHN C. SAUNDERS, M.D.¹

Chlorprothixene (Taractan),² a thioxanthene derivative, has been reported to be effective as a tranquilizer and an anti-depressant. This paper summarizes one year's experience with chlorprothixene.

The first study consisted of 70 female psychotic patients between the ages of 16 and 70 who had been continuously hospitalized for 4 to 31 years. Their diagnoses were: 63 schizophrenia, 4 involutional psychosis, mixed type, and 3 psychosis with mental deficiency. The patients had received various psychotropic drugs for at least 4 years with little or no improvement. For the past year they received the following drugs: 23 methotrimeprazine,³ 22 chlorpromazine, 8 thioridazine, 3 proketazine, 2 promazine, 6 chlorpromazine plus trifluoperazine, 5 methotrimeprazine plus trifluoperazine, and 1 methotrimeprazine plus proketazine.

At the beginning of the study the patients showed a variety of behavior. Although all were delusional and/or hallucinating, some were tense, agitated, irritable, hostile, and approximately an equal number were withdrawn, apathetic, disinterested. The previous medication was discontinued, and the patients were placed on chlorprothixene, beginning with 50 mgs. q.i.d. The dose was gradually increased until either satisfactory therapeutic results were achieved or disturbing side effects appeared. The highest dose was 400 mgs. q.i.d., but the most common dose range was 200-300 mgs. q.i.d.

The patients remained on chlorprothixene alone for 4 to 5 months. They were then evaluated as to changes in mental symptoms. Thirteen were considered moderately improved; *i.e.*, although still delusional

and/or hallucinated, they were more alert, more relaxed, more friendly, more interested in their environment; 31 were slightly improved, 23 unimproved, and 3 appeared worse, their delusions and hallucinations becoming more pronounced.

It was observed that chlorprothixene had an excellent calming effect without rendering the patient too drowsy (until high doses were reached), and also that the drug had only slight effectiveness in combating delusions and hallucinations. We decided, therefore, to combine chlorprothixene with another tranquilizer which had stronger antidelusional and antihallucinatory action. Ninety-one patients (61 from the first group and 30 chronically disturbed schizophrenics who had not benefited for 4 years from various psychotropic drugs) were given chlorprothixene plus another tranquilizer.

The following table summarizes the results after 3 to 8 months of therapy according to the combination used:

	MARKEDLY IMPROVED	MODER- ATELY IMPROVED	SLIGHTLY IMPROVED	UNIM- PROVED
Chlorprothixene + methotrimeprazine		7	10	5
Chlorprothixene + chlorpromazine		8	8	5
Chlorprothixene + thioridazine	1	9	6	4
Chlorprothixene + proketazine		8	7	3
Chlorprothixene + trifluoperazine		3	5	
Chlorprothixene + reserpine			2	

¹ Rockland State Hospital, Orangeburg, N. Y.

² Chlorprothixene was supplied by Hoffmann-La-Roche Laboratories, Inc., as Taractan.

³ Methotrimeprazine formerly had the generic name of levomepromazine.

In general, it can be said that when using chlorprothixene in combination, the choice

of the accessory drug will depend on the prominence or resistance of delusions and hallucinations and on the degree of tension and anxiety manifested by the patient. If the delusions and hallucinations are prominent or firmly entrenched, an accessory drug with a very potent antidelusional and antihallucinatory activity will be chosen, such as a member of the piperazine group of phenothiazine derivatives. However, if tension and anxiety are foremost, then an accessory drug with a stronger sedative effect (even though it may have a weaker antidelusional and antihallucinatory action) will be chosen, such as a member of the dimethyl group of phenothiazine derivatives.

The side effects when chlorprothixene was used alone were as follows: early in therapy, 1 patient complained of dryness of the mouth, 4 experienced weak spells associated with a fall in blood pressure, 6 complained of dizziness. These symptoms disappeared spontaneously without reducing the drug dosage. Later in therapy and only when higher doses were used, 15 patients showed signs of akathisia, 7 developed parkinsonian symptoms, and 3 manifested a form of dystonia in which trunk, shoulder girdle and neck were tilted to one side. These extrapyramidal symptoms responded partially or completely to benztropine

methanesulfonate (Cogentin). More serious was the frequency of grand mal seizures. Nine patients had 1 or more grand mal seizures with a total of 21 seizures. Five patients had never experienced seizures previously, whereas 4 who had undergone lobotomies years ago had been free of seizures for at least 3 years. The present seizures were not related to rapid raising or lowering of dosage, but seemed to be the result of the dose level. The 21 seizures occurred at doses of 175-400 mgs. q.i.d. By keeping the dose of chlorprothixene below the convulsive threshold for the individual, it was possible to prevent further seizures.

In summary, chlorprothixene's greatest merit in our study was its ability to calm the excited or anxious patient without producing excessive drowsiness, and with a minimum of extrapyramidal side effects. Since chlorprothixene exerts a weak antidelusional and antihallucinatory effect, it should be combined with another tranquilizer having more potent antipsychotic action, when treating patients whose delusions and hallucinations are prominent. No antidepressant effect of chlorprothixene was observed. Finally, the intramuscular injection of chlorprothixene, 25-50 mgs., was very useful in relieving acute excitement or anxiety.

THE RELATION OF HOUSING TO BEHAVIOR DISORDER

E. A. GROOTENBOER¹

As psychiatrist-consultant to the Municipal Service for Children's Psychological and Psychiatric Welfare, I have been deeply impressed by an almost stereotypical history given by the parents of children referred for diagnosis and treatment. The story goes like this: "We spent the first years of our marriage in my mother's home," or "in the home of my father-in-law." Before World

War II couples did not begin married life this way; they were able to be more independent of their parents.

As time went on, I began regularly to include questions regarding housing and intergeneration relationships within the home when it did not come out spontaneously as a part of the history. It was,

¹ Municipal Mental Hygiene Service, Rotterdam, The Netherlands.

Few places in the world are as short of housing as The Netherlands, and in this country probably no large city has had as severe housing shortages as Rotterdam which suffered enormous destruction during the War. Dr. Grootenboer has worked in the Child Psychiatric Clinic of the Municipal Men-

tal Hygiene Service of Rotterdam for some years. In a conversation with Dr. Paul Lemkau in the summer of 1961, she ventured her conviction that housing and behavior disorder in children were clearly related in many of her cases. He urged her to write out her impressions to share with American psychiatrists, and this present note is the result. Dr. J. A. J. Barnhoorn is the Head of the Rotterdam Municipal Mental Hygiene Service.

therefore, possible for me to review the new cases in the service for one month (July 1961) to see what proportion appeared to show important factors concerned with the subject of this note.

Of the 40 new cases in July 1961, 7 appear to have significant factors related to housing and circumstances directly associated with it. Of these, 2 were typical, 2 were not so significant, while 3 were rather atypical.

The reasons for the referral of the children to the Service were different for each child and gave no hint as to the complexity of the underlying situations. The following is a very brief summary of the 4 more typical cases of the 7 showing relationship to housing problems. First the 2 more typical cases :

1. G.K., male, born July 31, 1955; neurological and intellectual functions normal; older of two children, the second having been born November 29, 1956. Reason for referral: question of readiness for school promotion. Family history: nothing significant; mother hypertensive during pregnancy with this boy; father works in a milk plant.

At the time of this boy's birth the family lived in a room 6 x 10 and they continued in this room until the boy was 3. During her second pregnancy, the mother was unable to carry the patient downstairs, so he played indoors almost all the time until he was 3, when he began to get out with his younger brother. Just after this the family was able to get a 3-room house.

The child showed lovable, proper behavior at home. He showed some jealousy of his brother at first, but later his brother seemed to dominate. At the present time the boy does not play well with other children and becomes explosive and nasty at home also. He appears to be reacting to the delay in developing independence from his mother during the long period of existence in the single, small room.

2. J.V., male, born April 23, 1953. Neurologically and intellectually within normal range. Reason for referral: difficult behavior at home and, secondly, with other children at school. Family history: maternal grandfather probably alcoholic. The emotional atmosphere in the home is rather ambivalent and tense between the grandfather and his children; father is an elevator operator in the port.

At the time the child was born the parents were living with the maternal grandparents, an arrangement which continued until the

patient was 4. The child's family was described by his mother as "three mothers and two fathers." (An older, unmarried sister of the mother was in the home at that time.) Until the boy was 4, the parents had one room of their own but for the most part lived with the whole family in the small flat. The grandmother and aunt "spoiled" the child, ignoring the mother's opinions. The mother is a rather gentle and indulgent person. The father appears to be stable.

At the present time the patient's friends are ruffians not approved by the family. Apparently he has influence among his street companions and gets on well; home appears boring to him. He has difficulty falling asleep and does not get enough sleep; also has nightmares. He was once expelled from school, gets on well with his present teacher, but has great difficulty with other children, beating them and quarreling. He is unstable in mood, and generally expansive.

Two other cases are less typical of the group :

3. H.W., male, born May 9, 1956, older of two children, second born February 21, 1959. Intellectually and neurologically normal. Reason for referral: difficult to manage at home; poor sleep, but this improved since sister removed to another room. Family history: mother spent 6 years in tuberculosis sanitarium before her marriage. Father works in a factory which makes enamelled metal products.

At the time of the patient's birth, the family lived with paternal grandparents. Paternal grandfather is a rather autocratic man with his own ideas about child rearing; grandmother was fond of the child. The mother would take the baby (patient) out of its cradle whenever it cried, day or night. Her husband cannot "stand" crying children and as he at times worked nights, he had to sleep during the day. When the child was a year old, the family found a small house. Three years later they obtained a larger house and the boy had a room of his own.

Under clinic observation the child is happy and pleasant. He appears only to need some checks on his behavior and escape from the indulgent excuses his grandmother makes for him when he is nasty.

4. D.K., male, born January 24, 1955, first of three children; second, girl, born June 19, 1957 and third, girl, born February 22, 1959. Reason for referral: difficulties in behavior—aggressive toward other children in school. Neurologically and intellectually within normal

range. Family history : no positive findings ; father works as a clerk in an insurance office.

When the patient was born, the parents were living in two of the four rooms at the disposal of the maternal grandmother and aunt, an older unmarried sister of the patient's mother. The living arrangement continued until the third child arrived, when the patient was 4. The grandmother is rather strict in handling children. Until he was 4 the child was held down a good deal and not allowed very great freedom. At home he became rather dull and dreamy. He gave no one any trouble there ; his fantasy appeared to be enough for him. There were a few quarrels with his younger sisters.

With children on the street (after the family moved) he appeared unable to defend himself but then suddenly became aggressive, striking and pushing an uninvolved child after he had had trouble with someone else. His mother described him as rather lazy and more babyish than he should be at his age. On examination the child is tense and appears over-inhibited. Needs to be freed up in emotional reactivity.

The other 3 cases of the 7 are less typical in that, although there was little space available to the families, there was more abnormality in the parents, who were cold, egocentric, *etc.* The housing factor is not quite as clear-cut a factor in the etiology of these cases as in those already described. It must be stressed that the 4 clear-cut cases and the 3 less typical are taken from only one month's first admissions, 40 cases. The problems to be answered in these cases is whether or not, or how much, the difficult start these children have had has to do with later difficulties in their behavior. One cannot be certain; too few cases have been thoroughly analyzed and necessary control studies have not been done.

Nevertheless these cases and others in my clinical experience present certain similarities. Many show prolonged infantile "babyish" behavior which results in poor social adaptability most apparent in the school situation. The children appear unable to maintain their position *vis-à-vis* other children (as in *Cases 1 and 4*). *Case 2* eventually comes to non-acceptance of adult management, and *Case 3* shows somewhat the same development. There are other children whose early histories are different but who

also show these sorts of behavior disorders. Nevertheless, the housing factor does appear important.

The general situations may be broken down into certain situations which, theoretically, may be suspected of being related to the effect noted :

First, there is the lack of privacy, present, obviously, in all the cases. The privacy of the child is not the point, though this has been important in some cases, but the privacy of the young parents. This couple cannot free their children of the care of the other members of the household, regardless of how much they may wish independence in controlling the child. As one mother put it, "My child had three mothers and two fathers." Under these circumstances, whose voice means most to the child ? Or did the chorus deafen him to all the voices ?

Second, there is the factor of spoiling, the unexpressed competition between the parents and grandparents for the love of the child. The effect of spoiling continues for years, even though the nuclear family finds a home of its own.

Third, the inconsistencies in child care are multiplied. What the mother says is unintentionally reversed by grandma or grandpa. The child senses the dependent position of his mother, that there are others more powerful than she. His mother's faults are brought to his attention—in such small space he cannot avoid hearing family quarrels.

Finally, there is the lack of privacy of the parents in their sexual activities. This may result in excessive abstinence or, on the other hand, in the exposure of the child to their sexual intimacies.

In some cases, the results of the move by the parents to a home of their own after living with others are good. Sometimes, however, the first child represents to parents a relic of bad times in the past. The reaction resulting may leave the child lonely, always wanting to rejoin the grandparents. Not having achieved acceptance at home, emotional attachment to other children is difficult and appetite for social relationships may be decreased. The result is referral to clinic for all areas of social maladjustment : to school, to classmates, to all of society at times.

This housing factor appeared to be more troublesome during the severe shortage after World War II, because people were not accustomed to the kind of life they had to live. Before the War there were populous areas where families lived like clans more or less, but it was not necessary to stay with the clan unless one wished to. Nowadays simply everyone starts married life in somebody else's house. Furthermore, the old "clan-like" family life is considered old-fashioned and outmoded.

SUMMARY

Clinical experience has left the impression that housing situation of the nuclear family is related to the behavioral health of the children. Cases of varying degrees of typicalness are briefly presented to illustrate this situation. It remains to be seen how important and separable a factor this may be and to what extent it is important as an etiological factor.

It is hoped that having called the situation to attention more may be done to see that the child is protected from any ill effects.

USE OF AHR 437¹ IN BEHAVIORAL PROBLEMS

IRVIN A. KRAFT, M.D., JAMES H. DUFFY, M.D.,
CAHIT ARDALI, M.D., AND JUANITA T. HART, M.D.²

AHR 437 is a new agent [5-(2,6-dimethylphenoxy)methyl)-2-oxazolidinone] which was given a clinical trial on 12 children. It was one of a sequence of compounds studied in these children, thus its activity could be compared with chlordiazepoxide, mephenoalone, and amytriptyline.

Eight of the 12 children were in the 6- to 10-year-old group and 11 were boys. Eight were classified as hyperactive and 4

termed as behavior disorders and adjustment reactions. Five of the cases were carried on dosages under 800 mgm. per 24 hours; 7 received up to 1600 mgm. per 24 hours. The average length of treatment was 4 weeks. The results were that 66% of the children showed no change. The remaining cases showed slight alterations that could be called fair (+).

CONCLUSIONS

AHR 437 in a series of 12 children with hyperactivity and behavior disorders demonstrated no therapeutic effect in 66% of the cases.

SERUM GLUTAMIC-OXALACETIC TRANSAMINASE AND CEPHALIN-CHOLESTEROL FLOCCULATION TESTS IN ACUTE PSYCHIATRIC ILLNESSES

FERRIS N. PITTS, JR., M.D., AND GEORGE WINOKUR, M.D.¹

DeJong and St. John(1) reported from a state hospital population 44.6% of 56 female and 15.2% of 59 male patients with non-catatonic schizophrenia gave positive reactions to cephalin flocculation tests (CCF)

¹ Dept. of Psychiatry and Neurology, Washington University School of Medicine, St. Louis, Mo.

as compared with 6.9% of 121 control subjects. Zimmerman, *et al.*(2), could, however, find no increase in the percentage of positive CCF tests in a study of 175 schizophrenic and 210 non-schizophrenic chronic psychiatric inpatients as controls. Oltman and Friedman(3) could find no differences

in the incidence of positive CCF and thymol turbidity tests performed on various groups of 878 state hospital patients.

These studies were performed on schizophrenic populations in chronic hospitals; and sufficient data are now available to indicate that aberrations of liver function in chronically hospitalized schizophrenics are probably due to nutritional deficiencies, viral hepatitis, or helminthiasis in certain ward populations. Hepatic function has never been assessed in an *acute* psychiatric hospital in any systematic fashion, however, and the authors of the present communication decided that such a study would be of merit.

Nikolenko, *et al.* (4), reported the somatic disturbances observed before initial hospitalization and during hospitalization of 200 cases of schizophrenia. They noted that the onset of the disease was characterized by an "influenza-like" picture with symptoms of pyrexia, general malaise, headache, cardiovascular disturbances, and disturbances of the gastrointestinal tract and kidneys. This and other studies cited in the same volume were taken by the Russian Malis to indicate an exogenous infectious etiology of schizophrenia, viral in nature. If such an hypothesis were, in fact, true an increased incidence of positive CCF or serum glutamic-oxalacetic transaminase (SGOT) tests might be expected in acute schizophrenia or in other acute psychiatric illnesses with such an etiology if there were liver involvement or cellular damage in other organs.

Seventy-five consecutive admittances to the ward psychiatric service of the Renard Hospital and the Washington University Dept. of Psychiatry, St. Louis, Mo., were subjected to the usual clinical psychiatric evaluations and given a clinical diagnosis in accordance with the Standard Nomenclature of Mental Disorders of the American Psychiatric Association. Renard Hospital is a psychiatric hospital attached to a large general hospital and accepts all types of psychiatric problems for admittance but in a practical sense admits and treats only patients with acute psychiatric illnesses. On admission a CCF and a SGOT were obtained on each patient.

The CCFs were performed according to the method of Reitman and Frankel (5) and the SGOTs according to the method of Hanger (6). In the clinical laboratories of Barnes Hospital the CCF is negative if read 0, 1+ or 2+, and positive if 3+ or 4+ at 48 hours; the SGOT is negative if less than 40 units, borderline if between 40 and 50 units, and positive if above 50 units.

The results of the SGOT and CCF determinations are tabulated below by diagnostic category.

SUMMARY

A series of 75 consecutive psychiatric admissions were assessed for clinical diagnosis and laboratory determinations of CCF and SGOT. All CCF were negative. No instance of positive SGOT determination was found in the absence of specific and additional intoxication or metabolic dysfunction.

TABLE 1

DIAGNOSTIC CATEGORY	CCF		TOTAL	SGOT		TOTAL
	POSITIVE	NEGATIVE		50+ UNITS	50 OR LESS	
Schizophrenia	0	18	18	0	18	18
Manic-depressive	0	28	28	0	28	28
Conversion reaction	0	7	7	1	6	7
Anorexia nervosa	0	3	3	1	2	3
Anxiety reaction	0	1	1	0	1	1
Obsessive-compulsive	0	3	3	0	3	3
Passive-aggressive	0	2	2	0	2	2
Antisocial	0	1	1	0	1	1
Acute & chronic brain syndromes	0	12	12	4	8	12
Total	0	75	75	6*	69	75

* Assessment of each patient with elevated SGOT level revealed additional factors not common to the diagnostic group: these factors were alcoholism with hepatomegaly, starvation-ketosis, severe bronchial asthma, myxedema, and barbiturate intoxication.

tion. This would tend to negate assertions that schizophrenia and/or other psychiatric illnesses are associated with hepatic dysfunction or *significant* cellular damage in other organ systems.

IMIPRAMINE IN THE TREATMENT OF ADULT ENURETICS

EZRA E. DORISON, CAPT., M.C.¹ AND SHELDON BLACKMAN, CAPT., M.S.C.²

There have been clinical notes reporting favorable results through the use of imipramine for bed wetting. MacLean(1) reported favorable results with children. Munster, *et al.*(2), reported favorable results with hospitalized female psychotics ages 8-16.

This is a study of 30 male Army basic trainees who range in age from 17-23. They were referred to the Mental Hygiene Clinic, Fort Knox, Ky., with the complaint of enuresis. A double blind design was used with half the subjects given 50 mg. imipramine and instructed to take the medication at bedtime, and half the subjects given lactose, in a capsule of the same appearance with the same instructions. Assignment to the groups was on a random basis. The subjects returned to the Clinic after 2 weeks for follow-up.

Of the 15 subjects in the medication group, 6 reported improvement. Eleven of the 15 in the placebo group reported improvement. None of the 30 subjects reported any worsening of their condition.

Two types of comparisons may be made. One is between the rate of bed wetting prior to the medication being administered and the rate reported after 2 weeks of medi-

cation. This comparison should also be made for the control group. The second type of comparison is between the rates at follow-up of the medicated versus the placebo group.

By use of the Walsh Test(3) it can be shown that there is a significant (.05 level) decrease in the rate of bed wetting in the imipramine group. There is also a significant decrease (.01 level) in the placebo group.

The initial rates of the medicated and control groups were compared by a Mann-Whitney U Test(3). It was found that the groups did not differ initially on rate of enuresis. This is to be expected because of random assignment. A similar comparison was made at follow-up, and again there was no significant difference between the Tofrānil and placebo groups.

We have found that both Tofrānil and a lactose placebo were successful in significantly decreasing the rate of enuresis in a group of 30 Army basic trainees. There was no significant difference between the efficacy of the Tofrānil versus the placebo.

CASE REPORTS

THE USE OF HIGH DOSAGE DEPROL IN ALCOHOLIC AND NARCOTIC WITHDRAWAL

LAURENCE SNOW, M.D., AND KARL RICKELS, M.D.¹

Our previous work with meprobamate² has suggested to us that the drug might have proven efficacious in many instances of reported therapeutic failure, had an adequate dosage been used. The dose of any medication varies with the individual and we may frequently do ourselves and our patients a disservice if, in the absence of side effects, we discard a drug simply because no adequate response is met at or near the manufacturer's suggested dosage. Indeed there are times when even side effects may be used efficaciously if the workings of a drug are thoroughly understood. The following illustrative case may prove of interest.

The patient was a 47-year-old married, white male of the "driving executive type." His activities necessitated his working some 12 to 16 hours daily (frequently including Sunday) and under this strain he had become alcoholic, going on prolonged drinking binges, having "blackouts" and being apparently unable to stop drinking once he had started. Concomitantly he was habituated to barbiturates and purportedly had been taking various narcotics off and on for two years. We were asked to manage his withdrawal on an outpatient basis.

Our previous work with high dosage meprobamate suggested this drug as a tranquilizing agent. The somnolent side effect of high dosages of this drug suggested its value in a patient who was habituated to barbiturates. Deprol was used with the thought that the antidepressant and anticholinergic action of benactyzine would facilitate the effect of meprobamate.

The patient was started on Deprol, 5 tablets (2 gm. meprobamate plus 5 mg. benactyzine) and fluids. His wife and the attendant nurse were instructed that the therapeutic "unit" was 5 tablets and that any time the patient requested medication of any kind

he should be given one unit. The physician was in frequent but inconstant attendance.

The dosage, therefore, varied with the demands of the patient. The somnolent side effect of the medication kept the patient relatively bedfast and hence manageable, although he would sit on occasion on the edge of the bed and leave it several times daily to go to the bathroom. The patient was tired, but at no time was his sensorium unclear. On three or four occasions during the first 48 hours a slight slurring of speech was noted. On the third day the patient complained that Deprol made him slightly unsteady on his feet, but with the decrease of medication on the fourth day this complaint disappeared.

By the fourth day the patient was reasonably alert and was requesting less medication. Deprol was therefore gradually decreased and finally discarded at the end of the seventh day. At no time were any symptoms attributable to withdrawal from alcohol, barbiturates, narcotics or, later, from Deprol noted.

The actual dosage range used varied from 50 tablets of Deprol (20 gm. meprobamate plus 50 mg. benactyzine) on the first day, through 35 Deprol on the second and third day, 21 on the fourth day, to zero by the end of the seventh day. On the fourth day the "unit" was changed from 5 to 3 tablets so that, although the patient requested medication as frequently as before, he actually received less.

Unfortunately a prolonged follow-up was not possible. However, we make no claims for the medication as a cure for addiction or alcoholism, rather only as an agent for the facilitation of withdrawal.

SUMMARY

In this case Deprol in dosage as high as 50 tablets daily (20 gm. meprobamate and 50 mg. benactyzine) proved efficacious in alcoholic withdrawal. The authors feel that Deprol in the hands of physicians experienced in its use may prove efficacious in areas where hitherto failures have been reported because of inadequate dosage.

PROLONGED RETENTION OF URINE DUE TO AN ANTIDEPRESSANT DRUG

G. F. J. GODDARD, D.P.M.¹

A 73-year-old woman was admitted to hospital suffering from depression. Intellectually she was well preserved, showed only the degree of dementia appropriate to her years, had complete insight into her illness and was co-operative in every respect. Physical examination showed no abnormality in any system and she gave no history of physical disease. There had been no previous disturbance of bladder function.

Normally she would have been given ECT but was included in a trial group receiving antidepressant drugs and was given amitriptyline hydrochloride (Tryptizol), 50 mg., t.d.s. Fifteen days after the commencement of Tryptizol therapy she complained of pain in both loins, observed that she had not passed urine for over 24 hours and that she felt no desire to do so. A dribbling incontinence caused her great distress. Examination revealed a bladder up to the umbilicus with bilateral renal tenderness. Firm manual pressure of the distended bladder caused no pain or discomfort and no desire to micturate. She was catheterised and 62 ounces of urine were withdrawn.

Observing the manufacturer's warning that Tryptizol has "definite anticholinergic activity" the drug was stopped forthwith. The patient was examined daily thereafter, on each occasion the bladder was found to be distended and she required to be catheterised twice daily. On the fifth day, as no measure of voluntary control of bladder function had been regained, she was given carbachol, 5 mg. twice daily by subcutaneous injection for 5 days, but with no improvement in her condition. The bladder was found to be distended on each of the 5 days and catheterisation had to be continued, 50 ounces being withdrawn on one occasion. Carbachol was discontinued and, although partial bladder control was regained 6 days later, twice daily catheterisation had

to be resorted to for a further 17 days before normal bladder control was regained and catheterisation could be abandoned, i.e., 27 days after the onset of urinary retention.

At no time did the patient have any other symptoms or signs of autonomic dysfunction. Repeated neurological examination revealed no abnormality in the CNS. All reflexes were brisk and equal, the plantars were flexor, there was no paresis or spasticity of the lower limbs and all modes of sensibility, cutaneous and deep, were unimpaired. The blood W.R. was negative.

It is interesting to note that there was no potentiation of the anticholinergic effects of Tryptizol by imipramine (Tofranil) which was prescribed for her, 50 mg., t.d.s., on the 17th day of the period of urinary retention.

The patient stayed in hospital a further three months after this episode and during that time there was no evidence of further disturbance of bladder function, neither has there been on the two occasions she has attended as an outpatient in the six weeks since her discharge from hospital.

SUMMARY

A case is described of urinary retention lasting 27 days after 15 days' treatment with amitriptyline hydrochloride (Tryptizol). The interesting features are 1) the long duration of the condition after the drug was stopped and 2) the failure of a cholinergic drug (carbachol) to counteract the anticholinergic activity of Tryptizol.

The case demonstrates the necessity for daily examination for urinary retention of patients receiving amitriptyline HCL, particularly of cases who cannot be expected to make spontaneous complaint of urinary symptoms, due to dementia, depression or apathy.

HISTORICAL NOTE

KARL KAHLBAUM'S IDEAS ON PEDAGOGICAL TREATMENT OF MENTALLY ILL CHILDREN

ERNEST HARMS

Hidden away in the small print section of the 40th volume (1883) of the *Allgemeine Zeitschrift fuer Psychiatrie* is a reprint of a lecture given by Karl Kahlbaum before the 47th meeting of the Berlin Psychiatric Association on June 15, 1883. The 11-page reprint is entitled "About Nervously and Mentally Diseased Juveniles and Their Pedagogical Treatment in Institutions." Karl Kahlbaum has never received the acknowledgment he merits in the history of psychiatry. Those who reject him consider him "the fellow from a small East German private institution who made up so many strange and unnecessary words and titles." Those who esteem him consider him the originator of the concept of catatonia and hebephrenia. Kahlbaum's concept of hebephrenia was similar to the concept of pubertal neurosis held by British workers of the same period. His refined description of the condition must be designated the first realistically established concept of child psychiatry. In the lecture referred to, Kahlbaum pleaded for specific handling—what he called "pedagogical treatment"—of institutionalized juveniles. The point of view presented in the lecture shows a unique understanding of what we today call child psychiatry and represented a significant forward step in the history of the treatment of the mentally abnormal child. The lecture begins with an observation on the increase in the number of 14- to 25-year-olds afflicted with nervous and mental diseases of both the acute and chronic kind, including practically every known form of insanity. Kahlbaum, however, observed a specific juvenile deviation which took the form, on the one hand, of "ethical peculiarity and perversity," and, on the other, of "a more or less pronounced intellectual limitation and weakness." Because in a number of these cases one or the other of these symptoms was so dominant, it appeared justifi-

able to consider them two autonomic forms of mental disease. Although Kahlbaum was not able to provide proofs of the validity of his concept, he nevertheless presented—in 1883—a definite formulation of specific forms of juvenile mental disease.

In the lecture, Kahlbaum described in great detail what he called "ethical and intellectual pathology in youth." Ethical pathology, which can be of both negative and positive character, is seen in the form of laxity in responsibility and social and familial feelings, up to the point of crude egotism, and also in the form of ethical pathological "purism." In either form it disturbs the development of a life concept beneficial for the individual and others. In the case of intellectual weakness, the concern is not only with the inability to learn, but also with the "weak" tendency toward fantasy and lying, the latter condition also appearing in two forms—the "floride" and the "torpide."

Viewing these forms of juvenile psychopathology from the etiological aspect, Kahlbaum notes, one must first consider hereditary factors; in a preponderant number of cases the parents of such children are nervous people. Another element to be taken into account is physical disease and physical "pauperization," or undernourishment. Orphanage is also named as a frequent serious etiological factor in childhood psychopathology. Still another element is a false, too strict, or over-protective and lenient attitude on the part of the parents. Poor marital relations between parents and other negative circumstances of the family situation must also be seriously considered as important factors in the illness of the child. Kahlbaum was evidently well aware of the pathological social elements in child psychiatry which we today maintain were first recognized in our century.

Kahlbaum emphasizes individual treat-

ment as a basic factor in the treatment of institutionalized mentally ill young persons. First, physical impairment must be treated. Occupation and opportunities for study for those patients for whom study is possible are important elements in treatment. This broadened treatment of juvenile patients Kahlbaum calls "medical pedagogy," and this type of institutionalization he calls "medical pedagogium."

Kahlbaum developed a specific system for the "medical pedagogium": first, patients should be physically well and well-rested; they should not be overburdened with learning; free choice should be a major therapeutic element; physical and mental activity should be combined harmoniously. It is interesting that Kahlbaum emphasizes as another element in these cases—one that is today so frequently attacked first—the habitual and manic pattern of bad behavior. Kahlbaum describes in some detail the practical functioning of the "pedagogium" in his own institution: he had three resident teachers who were with the juvenile patients all day and who applied group and individual care according to the needs of the individual child. Handicrafts, art education, gymnastics, and gardening were also employed in treatment. As to academic instruction, Kahlbaum advised no imposing of specific instruction, but rather a con-

tinuation, as far as possible, of previous school status and instruction. He reported that he had been able to train his patients to the point of vocational adjustment. Some of his patients became booksellers and office clerks, and some became professionally active in the creative arts and in farming. Kahlbaum's methods demanded not only treatment for actual pathology, but character development and what he called "psychological propedeutic," by which he meant the imparting of a certain knowledge of controlled behavior. In spite of the emphasis on adjustment to the individual needs of the patients in his child psychiatric clinic, Kahlbaum instituted a definite daily routine: three hours of intellectual instruction followed by two hours of mechanical and artistic occupation in the morning, with afternoons given to trips, gymnastics, gardening, and games.

Kahlbaum's "pedagogium" was for a time famous in Middle-Europe, but it was soon entirely forgotten. It represents the first full-developed system of institutional care of mentally ill children, some of the treatment procedures of which are to be found today only in the most modern and progressive child care programs. Its initiator, a courageous pioneer, should not be forgotten or left out of the history of child psychiatry.

COMMENTS

TELL ME NOT IN MOURNFUL NUMBERS

Our mass media of communication have done a thorough job of dinning into the public that one of four Americans is doomed to have cancer. Lay and medical guardians of the nation's health do not tire of impressing us with figures about the prevalence of heart disease, arthritis, nephritis, obesity, diabetes, alcoholism, blindness, deafness, accidental injuries, and many other afflictions. I.Q. statistics "reveal" that a substantial portion of the population does not measure up to what the academicians have calculated as the criteria for intellectual normalcy. Some of our colleagues, reinforced by extra-professional Cassandras, keep telling us that at least one in every ten persons is sorely in need of psychiatric care. Thus, of 180 million people in the U.S.A., 45 million are said to be cancer victims or candidates, and 18 million supposedly cry out, or should cry out, for assistance because of emotional woes. If you add up all the numbers offered for the various and sundry maladies and anomalies, you may discover that there are more sick people around than the total number of inhabitants recorded by the census takers; you will be forced to conclude that the only way to account for this discrepancy is by making allowance for some overlapping.

What is the purpose in evoking this spectre of a lamentably decrepit nation? It is not too difficult to understand the zeal of campaigners in the fund drives for whatever illness it is that the public is admonished to make monetary contributions. In the established tradition of the advertising trade, the donor must be made to feel that he personally is the potential beneficiary of his largesse. The more widespread, the more universally threatening a disease is claimed to be, the more readily will the expected giver regard himself as included in the dire consequences of his failure to respond to the plea.

However, one is entitled to start with the premise that psychiatry, beyond trying to help individual patients, aims to alleviate

anxieties instead of creating them. If this is correct, it seems neither necessary nor wise for its practitioners to upset themselves and others with panicky anticipations of impending disaster. To be sure, the idea of prophylaxis has been a boon to mankind and the source of immeasurable progress. Prevention means the sum total of efforts to maintain health, not an exercise of throwing inkwells at a devil painted on the wall by a frightened imagination. Prevention means, for the community, the steady improvement of social conditions and, for the individual, a constructive modification of unwholesome trends. It definitely does not mean the kind of professional obsessiveness which wants to press every comer into the strait jacket of suburban propriety. Nor does it prescribe a frantic search for the pre-neurotic, pre-delinquent, and pre-schizophrenic. These are self-defeating terms; they denote a fatalism which foresees calamity even before there is any and paralyzes therapeutic enthusiasm. This tendency has recently assumed the form of trying to feed computers with data which would unfailingly predict future behavior. Fortunately the computers have no control over the feeders, and this deprives them of inexorability.

The story goes that several prominent university professors were engaged in a discussion of optimism and pessimism. One of the scholars gave an illustration of what he thought to be invincible optimism. He told of a young man who, on a delightful summer morning, walked along a beautiful shaded alley entertaining pleasant thoughts, when suddenly a bird dropped something on his bare head. Far from being irked, the young man explained happily: "How wonderful that cows are not flying around!" Dr. Adolf Meyer, who had sat silently through the conversation, pensively stroked his beard and said: "I do not believe that your man was an optimist at all, I am inclined to regard him as a profound pessimist—because he envisioned the worst."

Dr. Meyer was neither an optimist nor a pessimist. He preferred to speak of himself as a *meliorist*. Nothing is gained by the wholesale distrust in the present and future health of one's contemporaries. It is, of course, helpful to get the attitudinal and financial assistance of private philanthropic and governmental donors, but not for the price of declaiming numerical scares. It would be an insult to the nation to shout from the rooftops (as is sometimes being

done) that its physical and mental welfare depends solely on monetary appropriations. In spite of all the mournful numbers being circulated, the vast majority of our young, middle-aged, and "senior" citizens are sound, self-reliant, and productive people. Physicians, including psychiatrists, are ready to do their best to help those others who are in need of help and, as time goes on, to improve on that which is their best now. L.K.

STUDY OF BIOLOGY AS "UTILITY"

I think that knowledge of every kind is useful in proportion as it tends to give people right ideas, which are essential to the foundation of right practice, and to remove wrong ideas, which are the no less essential foundations and fertile mothers of every description of error in practice. And inasmuch as, whatever practical people may say, this world is, after all, absolutely governed by ideas, and very often by the wildest and most hypothetical ideas, it is a matter of the very greatest importance that our theories of things, and even of things that seem a long way apart from our daily lives, should be as far as possible true, and as far as possible removed from error. It is not only in the coarser practical sense of the word "utility," but in this higher and broader sense, that I measure the value of the study of biology by its utility.

—THOMAS H. HUXLEY (1876)

CORRESPONDENCE

DRUG EVALUATION IN PSYCHIATRY

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : There was a time when an ethical physician hesitated to give a report of his clinical impressions or statistics of results with a particular drug. He was afraid that he might be suspected of being biased and possibly paid by the drug manufacturer. In recent years the fear of a physician of exposing himself to this criticism has subsided, and rightly so. The drug industry has helped many patients and doctors in their efforts toward improvement of disorders which would not have been possible without close cooperation of manufacturer and clinician. The clinician is no chemist, and the manufacturer is no doctor. The necessity of close cooperation between the industry and the doctor is therefore generally acknowledged.

A little skepticism remains but this skepticism has been partly dispelled by the introduction of the so-called double blind study. That is : the patient did not know whether he received placebo or the drug and the doctor did not know which patient received what. Strenuous effort has been made to eliminate all accessory factors which might confuse the picture, and in some studies (the triple blind study) even the evaluating personnel did not know what therapy was employed and who was treated. Yet it appears that many, if not most, clinical studies on drug action in psychiatry are of very little value or misleading.

At a recent meeting of the American Psychiatric Association a majority of papers dealt with the evaluation of drugs. Many exhibits, as customary, tried to impress the onlooker with the value and advantage of one drug over another but in the eyes of an objective observer it appeared that most of these studies were a waste of energy, money and time of all concerned.

To substantiate this statement let us briefly examine one session at this meeting. The serious investigator, a psychiatrist who

has learned much chemistry and pharmacology, reported a statistical study on intravenous administration of an "antidepressant" drug. He had selected 60 depressed patients at random—all suffering from depressive symptoms—and felt that the random selection of patients made his study more objective. In his group he had psychotic depressive patients, manic-depressives, neurotic depressions, young patients as well as seniles, agitated depressions, retarded depressions, *etc.* He reported good results, mediocre results and no results in certain percentages of patients.

Now the various forms of depression admittedly not only vary in their predominant manifestations but are also admittedly based on different etiology. Without attempting lengthy reasoning let us assume the hypothetical fact that another investigator, a dermatologist for instance, reports instead of an "antidepressant" drug on an "anti-rash" drug. Does this sound like a Utopia ? It is not. Rash merely is a symptom and so is depression. What value is there in evaluating a drug or chemical by statistics when the drug has been administered to rashes indiscriminately, whether they are syphilitic, allergic or occupational in nature and by the same token what value is there in measuring results of one drug upon one symptom of mental disorders of various etiologies ? The symptomatic relief of the itch through a topical anesthetic in dermatology may be valuable. Similarly the relief of cough by an antitussant may be welcome but the patient may still die of lupus erthematosus or lung cancer. In many psychiatric conditions not even dependable symptomatic relief can be promised by any drug.

Unfortunately the etiology of mental illness is still vastly unexplored. Some is understood as for instance some organic disorder ; but in the field of functional disorders very little is known about etiology although some progress is being made too. This progress is what is needed. In other

words, basic research into the etiology of mental disorder is necessary because we know now that in spite of Freud's discoveries, only part of the cause is based on environmental and psychological factors. It is not useless to evaluate a drug and its effect on mental disorders caused for instance by neurosyphilis. Such evaluation is helpful because we know the etiology of the disorder. But the tremendous effort

spent in an attempt to evaluate drugs in the treatment of disorders the etiology of which is entirely unknown by observing the effects on one of the symptoms seems a tremendous waste of able minds. These minds could be put to work on more constructive tasks instead of confusing the clinician with reports and statistics which mean little or nothing.

PARENTERAL MAGNESIUM AND DELIRIUM TREMENS

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : Our previous clinical note (Am. J. Psychiat., 118 : 1042, 1962.) on the treatment of severe acute brain syndrome attributable to alcohol indicated that magnesium sulfate was of value particularly in preventing the development of delirium tremens.

Fortunately we evaluated 100 additional cases in a similar double blind study except

that the cases were randomly assigned to magnesium sulfate or the saline placebo by code number. The statistical values previously observed were not present in the extended series and no difference was noted in either the prophylactic or therapeutic response of the two groups at the dosage level used.

Note by the Editor.

In a letter from R. George Christie, M.D., referring to a quotation attributed to Mr. N. Khrushchev used as a filler in the September issue of the Journal is the following interesting information :

"Congressman Morris K. Udall (NEW REPUBLIC 7 May 1962) asked the Library of Congress to check this out and he got the following reply : 'We have searched

the Legislative Reference Service files, checked all the standard reference works on quotations by Khrushchev and consulted with the Slavic Division of the Library of Congress, the Department of State, and the US Information Agency, in an attempt to determine the authenticity of this quotation. From none of these sources were we able to produce evidence that Khrushchev actually made such a statement.'"

SPECIAL REPORTS

THE CURRENT STATUS OF POSTGRADUATE PSYCHIATRIC EDUCATION

HENRY KRystal, M.D.¹

The following is a report of a survey of the status of postgraduate education for practicing psychiatrists given by American colleges—exclusive of psychoanalytic institutes affiliated with medical schools. The survey received responses from heads of departments of psychiatry. Of the responding colleges, 43 indicated a conviction that postgraduate education was the responsibility of medical school psychiatry departments not only in the areas of education for general practitioners and other specialists, but also for psychiatrists. However, only 19 departments of psychiatry had in the past or were now offering such courses (51% of respondents, 35% of medical schools). Five other colleges were planning or preparing postgraduate psychiatry teaching for the near future. Five respondents denied this area to be the responsibility of medical schools, feeling that this function is carried out by professional societies.

The great majority of respondents reported good to excellent response by their psychiatric communities in terms of their active participation in the courses. Two-thirds, however, cautioned that such a response can only be expected after a careful preparation of the psychiatrists in practice for the idea of continuing education. When the availability of such courses was adequately publicized, the attendance was usually adequate, especially by the younger men.

The respondents indicated that psychiatrists tended to take the continuing education courses for the following reasons: 1. "To fill in gaps in training" (5 responses); 2. "To prepare themselves for the boards" (3 responses); or 3. "To get help in the handling of transferences" (5 responses). Other respondents emphasized those areas

of psychiatry in which much research is being done, necessitating that the practitioner "keep up" with them, and refresh his training periodically. The "rounding out" of one's training as a means of complementing a one-sided orientation residency training seemed to be of special concern to the educators.

The responses to our questionnaire indicated that preconceived notions about the subjects of the courses to be given are not always supported by experience. This is suggested by the fact that the psychiatry departments which had offered postgraduate courses in the past listed the subjects most highly recommended in a different order than the inexperienced group.

The preferred-subject responses of the experienced group, arranged in order of decreasing popularity, were: 1) psychotherapy; 2) addictions; 3) genetics; 4) psychiatric emergencies; and 5) age-specific conflicts. The respondents who had not given postgraduate courses for psychiatrists in the past recommended subjects in the following order: 1) psychotherapy; 2) depressions; 3) psychiatric emergencies; 4) new drugs; and 5) psychophysiological research. Other topics were recommended by both groups with equal frequency or showed no particular trend.

The impression gained from the responses was that there was a certain timidity about offering postgraduate courses without proof of a popular demand for them, but once offered the courses evidently were continued permanently.

SUMMARY

A questionnaire sent to the departments of psychiatry of the colleges of medicine in the United States revealed that 82% of responding colleges felt that continuing psychiatric education is the responsibility of the medical schools. Since 62% of the col-

¹ Dept. of Psychiatry, Wayne State University College of Medicine, Detroit, Mich.

leges responded, this represented about 52% of all American medical schools. Only 19 responding colleges were offering such courses at the time, and five more of them had such courses in preparation. Most respondents felt that a preparatory period of advance preparation via advertising and

notices addressed to the practicing psychiatrists should precede the offering of the courses and would substantially improve the response.

There seemed to be little question in the minds of our respondents that there is a need for postgraduate psychiatric education.

TRANSCIENCE

We traveled empty-handed
With hearts all fear above,
For we ate the bread of friendship,
We drank the wine of love.

Through many a wondrous autumn,
Through many a magic spring,
We hailed the scarlet banners,
We heard the blue-bird sing.

We looked on life and nature
With the eager eyes of youth,
And all we asked or cared for
Was beauty, joy, and truth.

We found no other wisdom,
We learned no other way,
Than the gladness of the morning,
The glory of the day.

So all our earthly treasure
Shall go with us, my dears,
Aboard the Shadow Liner,
Across the sea of years.

—BLISS CARMAN

NEWS AND NOTES

LEGAL TEST FOR INSANITY.—In "The Insanity Defense—An Effort to Combine Law and Reason," in the *University of Pennsylvania Law Review*, 110 : 771, 1962, Richard H. Kuh reviews various tests of criminal responsibility, including the McNaughton Rules, Irresistible Impulse, the Durham Standard and the American Law Institute Proposal. He has set out the arguments for and against each test lucidly and objectively. His text is documented with references to both medical and legal authorities of a thoroughness unsurpassed by any similar writing which the reviewer has read anywhere.

The latter part of the article contains a "proposed psychiatric offender law." The essence of the proposal is that these issues be tried by a judge without a jury. This has been suggested before but not in the form herein proposed. Many of the objections are dealt with so as to make the proposal a practical one. There is one objection that is not mentioned: in a jurisdiction where the death penalty is mandatory for murder, there is likely to be an aversion to vesting the adjudication in a judge alone.

The article is highly recommended for either psychiatrists or lawyers as an authoritative source of information about the various legal tests for insanity as a defence in criminal cases.

K. G. G.

TWENTY-THIRD INTERNATIONAL PSYCHO-ANALYTICAL CONGRESS.—This Congress will take place in Stockholm, Sweden, under the auspices of The Swedish Psycho-Analytical Society, from July 28 to August 1, 1963, inclusive.

Inquiries with regard to the administration of the Congress should be addressed to L. Börje Löfgren, M.D., Chairman, Congress Organising Committee, Narvavägen 25, Stockholm Ö, Sweden. Those wishing to present papers should contact the Chairman of the Program Committee—David Beres, M.D., 151 Central Park West, New York 23, N. Y.

DR. ROSSMAN WILL HEAD NEW BRONX HOSPITAL.—Dr. I. M. Rossman, director of the Gowanda (N. Y.) State Hospital, has been appointed to take over the administration of the Bronx State Hospital which will be opened in 1963. This institution is the first new mental hospital to be built by New York State in 30 years.

Dr. Rossman graduated in arts and medicine from the University of Toronto and has been in the New York State service since 1930. He has directed the Gowanda hospital since 1954.

ALLAN MEMORIAL INSTITUTE.—Dr. D. Ewen Cameron, Chairman of the Dept. of Psychiatry, McGill University, and Director of the Allan Memorial Institute, reports that work has begun on the new research building which is expected to be completed in about nine months. It will be a five-story structure. It is a University building located with direct connection to the Institute.

One hundred and five graduate students representing 31 nationalities are enrolled in the four-year diploma course in psychiatry at McGill.

THE SOUTHERN CALIFORNIA PSYCHIATRIC SOCIETY.—The Society will hold its convention meeting October 19-21, 1962 at the Hotel Biltmore in Santa Barbara, Calif.

The principal address will be given by Louis J. West, M. D., Professor of Psychiatry, University of Oklahoma. Papers and workshops will deal with day-care programs and conjoint family therapy.

NATIONAL INSTITUTES OF HEALTH RESEARCH IN AGING.—Three brochures have been issued by the NIH, *Research Highlights in Aging*, *Activities of the National Institutes of Health in the Field of Gerontology*, and *Research Programs in Aging*. Single copies are available from the NIH on application.

BIOGRAPHY OF ADOLF MEYER.—Pertinent material—letters, papers, personal reminiscences, photographs, and other items of biographical interest—are being solicited by Miss Eunice E. Winters and Miss A. M. Bowers. Please communicate with them at 4305 Rugby Road, Baltimore 10, Md.

THOMAS W. SALMON MEMORIAL LECTURES.—Professor René Dubos, a microbiologist and experimental pathologist who has been associated with the faculty of the Rockefeller Foundation since 1927, will de-

liver the annual Thomas W. Salmon Lectures at the New York Academy of Medicine, December 3, 1962 at 4:30 and 8:30 p.m.

His topic will be "Mind—The Mirror of Society." Topic of the afternoon lecture "Insanity as Depicted by Artists of Different Civilizations"; of the evening lecture "The Adaptive Potentialities of Man."

The Salmon Lectures have been given annually since 1932 and are designed as permanent contributions to the field of medicine and are later published in book form.

BOOK REVIEWS

DRUG ADDICTION—CRIME OR DISEASE ?
(Bloomington : Indiana University Press,
1961, pp. 173. \$2.95.)

The sub-title of this book is "Interim and Final Reports of the Joint Committee of the American Bar Association and the American Medical Association on Narcotic Drugs."

The back cover of this booklet states : "The alarming increase in drug addiction since World War II has made the narcotic problem one of the most pressing in the United States today." A few facts on this "alarming increase" appear appropriate : There was a continuing decrease in the number of addicts in the United States between World War I when the military service rejection rate for addiction was one in 1,500 and World War II when the rate was one in 10,000. During the World War II period the control of commerce and the importation of narcotic drugs into the United States reduced the number of addicts in the United States to a minimum. The number of white addicts has not increased significantly since World War II. Of the 100,000,000 white persons 18 years of age and older in the United States, less than 12,000 have been known to be addicted at any time during the past five years. After World War II there was a significant increase in addiction among the Negro, Puerto Rican and Mexican population groups in some of the largest cities. About 33,000 are known to have been addicted at some time during the past five years. The total number of known addicts in the United States today (45,000) is less than it was prior to World War II.

The introduction tells the reader that he can choose between two opposing schools of thought on how to deal with drug addiction—one school regards addiction as an activity properly subject to police control and the other regards addiction as a disease. A clearer view might be obtained with an objective perspective that would differentiate views on the control of the production and distribution of narcotic drugs—an international and domestic regulatory problem—from views on the treatment of the narcotic drug addict—a medical and rehabilitation problem. These two views are compatible and do not require the adherents to attack each other and dissipate energy that could be used in a constructive manner.

A facsimile of the original cover of the "Interim Report of the Joint Committee of the American Bar Association and the American

Medical Association on Narcotic Drugs" is reproduced and indicates that it was "Confidential—Not for Distribution." This is surprising because a copy sent to me in 1958 had no such label and copies were distributed freely at a meeting in 1958. Since a facsimile of the cover of the "Comments on the Interim Report by the Advisory Committee to the Federal Bureau of Narcotics" is on the opposite page, it appears that the objective is to show that there was a breach of faith committed by the Bureau of Narcotics.

The brief "Interim Report" of the Joint Committee is included and has a lengthy Appendix A which is a collection of information containing many partial and complete quotations. Some are used to support the recommendation for the establishment of an experimental clinic which would dispense drugs to addicts if the staff did not succeed in taking and keeping the addict off drugs. This appears to be a unique approach for alerting behavior—rewarding failure. Pavlov missed this.

Appendix B of the "Interim Report" reviews the practices of countries in Western Europe and the United Kingdom that never have had a drug addiction problem similar to that in the United States. The conclusion was reached that the experience there has been different from our own. The Council on Mental Health of the American Medical Association stated in its report in 1957 that consideration of addiction in other countries provided little useful information because of the many differing factors. The second conclusion in Appendix B was that international controls on the production and export of narcotic drugs are unlikely to be a major factor in solving the United States problem. This is puzzling in view of the results obtained by control of commerce in World War II. It will be a blow to the many knowledgeable people who have worked successfully to reduce the number of countries producing and exporting opium. The creation of an addict requires both an unstable person and available narcotic drugs. There has been considerably more success in decreasing the amount of available drugs than in decreasing the supply of unstable people.

A few pages at the end of the booklet present the Final Report of the Joint Committee with its five recommendations for medical and legal research.

The Joint Committee gave little attention to the role of the medical profession in relation to

addiction because the Council on Mental Health of the American Medical Association covered this in its 1957 report. The summary and recommendations of the Council Report are included at the end of the booklet. The full report was in the *Journal of the American Association*, Vol. 165, Nov. 30, Dec. 7, and Dec. 14, 1957. More information useful to a physician is in that brief report than in the reviewed booklet whose main body is two lengthy appendices.

It is hoped that this booklet will not be followed by one with an equally quizzical and alluring title "Dope Peddling, Crime or Disease?" as a disguise for the "Comments on the Interim Report by the Advisory Committee to the Federal Bureau of Narcotics."

JAMES V. LOWRY, M.D.,
Bethesda, Md.

NARCOTICS AND THE LAW: A Critique of the American Experiment in Narcotic Drug Control. By *William Butler Eldridge*. (New York: New York University Press for American Bar Foundation, 1962. \$5.00.)

Any one interested in the subject should read this book, not for another "plan" or ready-made solutions but for critical analysis of the problems (plural) involved in narcotic drug addiction. Mr. Eldridge gives judgments as well as data and is open to both argument and further research, but his contribution is one of objective analysis rather than emotional debate.

The background chapters give a sweeping view of the history of the subject from antiquity to the present, with the changing attitudes: the British forcing the opium trade on China; the literary romanticizing of the "milk of Paradise"; the spread of medical addiction as the "army disease" in the United States during the Civil War; the promotion of addiction by the patent medicine business with well advertised narcotic cures for all diseases, including addiction; then medical and public concern bringing attempts at control, with the Harrison Act of 1914 designed to buttress State laws and marking what Mr. Eldridge summarizes as "an effort which set out to control the non-medical use of narcotics and evolved into the prohibition of non-medical uses and the control of medical uses."

After examining some of the currently publicized beliefs regarding addiction, Mr. Eldridge describes the efforts of the American Medical Association and the American Bar Association to substitute a research approach for subjective opinion and to study the actual

effectiveness of present narcotics policies in the United States. The heart of the book is "An Empirical Evaluation of the American System" based on a study of the Federal Government's narcotics policies and of the 4 states with most of the narcotic drug addicts (New York, California, Illinois and Michigan); 3 states (New Jersey, Ohio, and Missouri) where increased penalties had been claimed to be effective in reducing the narcotics problem; and the District of Columbia, chosen because of its administration by the national government. The American Bar Foundation conducted the project, and Mr. Eldridge was the project director. Aside from the specific results of the project, it is noteworthy as part of the American Bar Foundation's program to relate law more adequately to social facts through multidisciplinary research.

The evaluation is frankly preliminary. Its most emphatic conclusion is that we need much more, and more reliable, information as a basis for policy-making. Mr. Eldridge does, however, question certain provisions of the present state or federal laws, e.g., legislative restrictions on a physician's choice of treatment in good faith and in the course of his professional practice; the punishment, in some states, of addiction, per se, as a crime (which has since been held unconstitutional by the U. S. Supreme Court); requiring addicts to register; prohibitions that prevent the use of parole and probation, especially parole, in narcotics offenses as they are used in other criminal offenses. He also comments directly on various proposals for narcotics control—from clinics to life-time confinement—and in doing so of course he becomes controversial.

The most concrete recommendation, made in the interest of "accumulating definitive information," is to set up a national agency which with similar state agencies would seek to "obtain information on all salient aspects of addiction and traffic" and "to assure complete reporting from all agencies concerned with the problem." The recommendation stresses that the agencies "not be wedded to the agency responsible for enforcement"; yet the data suggested are all to be obtained from enforcement agencies. These data, however, are suggested as minima; there is room for other methods of obtaining information on the health aspects of narcotics control through health agencies. Perhaps those most familiar with the problems of obtaining such information, such as those who have already made a start in California, New Jersey and New York, can best design the methods of accomplishing this objective.

Each group concerned with narcotics probably will agree with the conclusion: "What is needed basically is a recognition that the whole narcotics problem cannot be lumped together and given to legislators, enforcement agencies, hospitals, or doctors. There must be a realignment of responsibility and a genuine spirit of cooperation in areas which overlap in interest." This, of course, is easier said than done, since the addict is one person even though he be both sick and a law violator. Mr. Eldridge tries to distinguish the areas of 1) enforcement of laws against illicit traffic, 2) treatment of addiction, and 3) overlapping interests. Who then should judge whether the addict who buys narcotics solely for his own use, and, by definition, has lost the power of self-control over his own use, is to be punished as a purchaser, involuntarily hospitalized for treatment, or left to the professional judgment of his physician? Mr. Eldridge's suggested dichotomy of law enforcement and treatment of addiction does not answer such questions. The live issues seem most likely to be in the area of overlapping interests. But with the help of such efforts as that of the American Bar Foundation perhaps the time is ripe to move from thesis and antithesis to at least a further attempt at synthesis.

EARLE V. SIMRELL,
Washington, D. C.

THE VIRGIN'S CHILDREN. By William Madsen.
(Austin: University of Texas Press, 1961,
pp. xv + 248. \$4.50.)

This book presents an anthropologist's very attractive and informative account of life in a modern village populated by descendants of the Aztecs. The village of San Francisco Tecoposa consists of 800 Indians who still speak the Aztec language of Nahuatl pretty much as it was spoken at the time of the descent of the Spaniards upon the Valley of Mexico.

In addition to its value as a description of a non-literate culture, the present volume throws much light on the mechanisms of culture, specifically of acculturation, so that the conclusions which can be drawn from a study of this kind may have very real practical value in facilitating cultural change in other cultures. Pagan gods were very easily replaced for these Aztecs by Christian ones because the latter demanded no great change in the role played by their traditional gods. Nevertheless, there has been a considerable change in their conception of the mother goddesses, and the change has been considerably for the better.

The book is excellently illustrated, and some

of the most interesting illustrations are by a ten-year-old Tecoposa boy. A most valuable book.

ASHLEY MONTAGU, PH.D.,
Princeton, N. J.

MINDS THAT CAME BACK. By Walter Alvarez, M.D. (Philadelphia, New York: J. B. Lippincott, 1961, pp. 384, incl. annotated bibliography and index. \$5.95.)

Dr. Alvarez, former professor of medicine at the University of Minnesota, for many years consultant in internal medicine at the Mayo Clinic, has been known to thousands of readers across the continent through his syndicated medical column in eighty-odd newspapers. Indeed, the off-hand conversational style of his column is reflected in the present book, the writing of which, he says, of all his books has given him the most pleasure.

Here he has recorded the histories of more than 60 persons suffering from various forms of mental disorder, many of whom have later given most instructive accounts of their pathological history—persons such as Clifford Beers, or have incorporated their experiences in their literary works, notably Dostoevsky, van Gogh, Strindberg, de Maupassant.

It was Clifford Beers' *A Mind That Found Itself* (1908) which Alvarez read shortly after it was published, that set him to collecting books of a similar nature, abstracts of which are included in the present volume. He eventually extended his enquiry to include some eccentric characters that would not be classed among the strictly psychotic—alcoholics, epileptics, drug addicts, blind and deaf persons, and those otherwise crippled, also hoboes, prostitutes, sex perverts (now euphemistically referred to as sex deviates).

A particularly interesting feature of this book is the annotated bibliography containing some 400 classified titles (all drawn from the author's own library) representing the field he has covered.

Here will be found *The Story of Mary MacLane by Herself*, *Le Horla* of de Maupassant, Nietzsche's *My Sister and I*, Thigpen and Cleckley's *The Three Faces of Eve*, the cases of Nijinsky, Cowper, George Fox, Charles Lamb, Hazlitt, Strindberg, Mary Astor, Jean Cocteau, De Quincey, Baudelaire, Baron Corvo, Lord Alfred Douglas, André Gide, etc., etc. . . . A few patients who have undergone psychoanalysis tell their stories, e.g., Lucy Freeman, "who says she was always mixed-up about sex and other things, tells of five years of psychoanalysis, and her marriage, which soon went

sour. It is not clear how much good her analysis did her."

The author introduces his book with "A Brief Description of the Several Types of Mental Aberrations," which shows the risk one takes who tries to make a satisfactory psychiatric diagnosis. "Most of us presumably normal persons are mixtures of sanity and insanity." He refers to Earl Bond's *One Mind Common to All* (1958). "His thesis is that if we were to set up a scale of sanity, running from one to ten units, with a 'crazy' man at the bottom and, let us say, Benjamin Franklin at the top, most of us would rate around five."

C. B. F.

HANDBOOK OF PHYSIOLOGY. 3 Volumes. Edited by John Field, and H. W. Magoun. (Baltimore: Williams & Wilkins, respectively 1959, 1960, 1960, pp. 779, 660, 572. \$22.00, \$20.00, \$20.00.)

Scientific writing can be divided into three classes. First there are the reports of original observation and thought presented in the scientific periodicals and as monographs. The second class is comprised of review articles in which an expert in a field summarizes and attempts to place in proper perspective the papers in his own field which have appeared since a previous review was written. The third class of scientific writing is the textbook in which the author surveys the whole body of knowledge of a subject and presents it in a systematic organized form. In planning to write a textbook it is necessary to consider two variables. These are the delineation of the subject and, secondly, the size of the volume to be produced. In theory these two variables can be completely independent, yet usually they are closely related. The result is that most textbooks represent a compromise between the necessity to limit the size of the volume and an adequate presentation of the material.

During the 19th century the great German "handbuchs" were the most complete and authoritative textbooks of medical knowledge. The concept behind these volumes was to present in detail the whole body of knowledge with little or no regard to the size of the volumes. In the mid-nineteenth century this was not an unreasonable task, but with the tremendous growth and the unprecedented expansion of the medical literature in the 20th century, the need has become more urgent and the task more impossible. In 1953 the American Physiological Society undertook to publish a *Handbook of Physiology*, that would be comprehensive and detailed, yet critical and giving proper

emphasis to the classical, well established knowledge as well as to add the newer developments. The society appointed Professor John Fields at the University of California to be Editor-in-Chief with Professor H. W. Magoun as Editor of the section of neurophysiology, which has now appeared. This consists of three large quarto volumes totaling almost 2000 pages. Each of the 81 chapters has been written by a recognized authority in the field. Inevitably the material is dominated by the recent advances in neurophysiology that have been made possible by the introduction of modern electronic techniques. These newer methods have brought about a revolution in neurological thought. They have made possible the stimulation and recording from deep structures within the nervous system of almost intact animals. In many cases the neurophysiologists have been able to demonstrate interconnections before the anatomists describe them. It has also permitted study of the various functions performed by the cytologically different portions of a single nucleus. In spite of this, the classical work of such authors as Sherrington and Cajal is not neglected but serves as a landmark to which more recent findings can be related, and placed in the proper perspective.

The first volume, after an excellent historical review, deals with the physiology of the single neurone and discusses the electrical activity of the brain as a whole. Also in this volume sensory mechanisms and vision are discussed. The second volume is devoted to the motor system and the central regulatory mechanisms. The final volume deals with higher brain functions such as learning, behaviour, consciousness, perceptions, etc. The latter half of the volume is devoted to metabolism, haemodynamics, cerebrospinal fluid and the blood brain barrier.

The quality of individual chapters varies, but the average is high. Where controversy exists the author naturally has expressed his own views, but on the whole the evidence is fairly presented. A few of the chapters fall below the general standard of the volumes, even so they are of high quality. The indexing is well done and adequate. The placing of the figures to the center fold of the volume and the captions to the lateral margins of the page rather than centering them is rather distracting, and detracts from the symmetry of the page.

These volumes are rapidly becoming a standard reference text for neurophysiology. They have achieved the objectives of the American Physiological Society in that they are comprehensive, correct in detail, and authoritative. They provide the serious student an

adequate background for further study, or the practitioner with a review and summary of modern developments and thought. The size of the volumes would make it a major task to read them in entirety, but enhances their value as a reference work. It is inevitable that they will soon be out of date for in a rapidly advancing field of knowledge new discoveries will be added; yet the editorial policy has been to give an integrated picture of present knowledge, and this will provide a solid foundation for understanding future developments. These volumes should be readily available to all workers in the neurological sciences.

JOHN W. SCOTT, M.D.,
University of Toronto.

PSYCHOANALYSIS AND RELIGION. By Gregory Zilboorg, M.D. (New York: Farrar, Straus and Cudahy, 1962, pp. 243. \$4.50.)

The late Gregory Zilboorg here comes to grips with the widely-held conviction that psychoanalytic doctrine is incompatible with religious faith. His verdict is that this conviction is wrong, and that one can at the same time be a devoted practitioner of religion and a true believer in psychoanalysis. Zilboorg was something of an authority on religion. Born of Jewish parents, he abandoned the faith of his fathers when he came to the U. S. A. in 1919. He then became a Quaker, but stopped going to Friends' meetings in 1939. Thereafter he married an Episcopalian and in 1954 became a Roman Catholic.

Why is psychoanalysis supposed to be hostile to religion? One reason is that Freud was anti-religious himself. Another is the feeling on the part of some religious people that psychoanalytic sessions compete with confession. A third factor is that standard analytic doctrine is supposed to hold that religious faith is a delusion (or at best a neurosis) and that religious ritual is a "compulsion." Another reason is the analyst's unwillingness to judge virtue and vice, good and evil, moral and immoral. Religion must make such judgments—can religious practices survive without condemning sin and, therefore, without acknowledging the existence of sin? The analyst is non-judgmental.

Zilboorg feels that none of these factors is serious enough to destroy the potential rapport between psychoanalysis and religion. Thus, he clearly differentiates a religious confession from an analytic interview in that unconscious guilt is poured out to the analyst but conscious guilt to the priest. If the penitent does not feel glad when doing his penance, then his guilt feeling has unconscious roots, and this,

Zilboorg suggests, makes it "a psychopathologic problem—a case for the analyst not the priest."

The analyst's reluctance to make moral judgments does not worry Zilboorg—it is, he thinks—simply a case of each shoemaker sticking to his own last. Psychiatrists should not be moral philosophers and clergymen should not be psychiatrists, so there is no conflict here—each operates in a different and non-conflicting orbit. Some religious people think that psychoanalysis has too strong a sexual tincture. Here too, Zilboorg sees a rapprochement. By now many religious experts have decided that sex is here to stay and accept its role in human anxiety, unhappiness and guilt. Furthermore, Zilboorg explains that what Freud meant by the "genital" phase, was not sexual maturity in a biologic sense, but rather that "sensual infantile egocentric drives have become adult and altruistic love for other people."

Obviously some of Freud's concepts are clearly unacceptable to religious people. Here Zilboorg retorts that you are free to reject that aspect of Freud's philosophy without losing faith in psychoanalysis. In this phase of his work, Freud—who was otherwise, Zilboorg agrees, something of a genius—was on the wrong track. Freud's anti-religious feeling was personal and basically neurotic and his disciples should not be influenced by it, argues Zilboorg. The author believes that as a 3-year-old, Freud had a kind of "primal love" attitude towards his Moravian (and Catholic) nurse and never quite solved the Oedipus situation there. Zilboorg suggests that Freud was neurotically ambivalent in his attitude towards religion. His fiancée, later his wife, was a practicing and orthodox Jew; Freud was not: thus provoking some anxiety. Freud asserted that Moses was really an Egyptian. It thus seems as if Freud had to reject Judaism and then all religion because of some inner need in himself.

Some religious people have an uneasy feeling that if psychoanalysis prospers, religious faith decays. Actually, Zilboorg says, psychoanalysis as a scientific doctrine no more threatens religion than the heliocentric theory of Newton's physics damaged religious faith in his day. ("Man's faith" comments Zilboorg, "is destroyed more by wars than by scientific discoveries.") Far from hurting religion, psychoanalysis has actually contributed to the greater understanding of religion. (Zilboorg's reasoning here is that the more we know about human beings, the more firmly religious truths are established.)

Zilboorg yields to no one in his admiration of science. But he points out that, for all his

vaunted scientism, Freud actually relied a good deal on myths, sagas and fantasies, and he never seemed to understand that there certainly *can* be knowledge outside the frontiers of science, that a scientific knowledge of the mechanics of nature would tell us nothing about its purpose of first cause. (The only discipline that has a right to study the first cause is theology, suggests Zilboorg.)

Edited by Zilboorg's widow, this text consists of eleven essays, the earliest printed in 1939 when Zilboorg was abandoning Quakerism; the latest written in 1958 after his conversion to Catholicism. It is too bad that no index was provided, because this book is full of epigrammatic wisdom to which the reader will want to refer frequently. There is much here to disagree with, but it is all presented with fluency, clarity, and shining sincerity.

HENRY A. DAVIDSON, M.D.,
Cedar Grove, New Jersey.

PSYCHOTHERAPY IN THE SOVIET UNION. Translated and edited by *Ralph B. Winn*. (New York: Philosophical Library, 1961.)

This book consists of 35 papers read at the conference on psychotherapy held in Moscow in 1956. They are divided into six main groups: Theoretical Problems of Psychotherapy, Psychotherapy of Neuroses, Psychotherapy of Psychoses, Treatment of Alcoholism and Smoking, Psychotherapy in Somatic Ailments and General Problems.

As in most collections, the papers are of uneven quality. The lead paper by V. N. Miasischev on theoretical questions of psychotherapy is by far the most informative. If one deleted the ritual obeisance to Pavlov and the ritual attack on Freud (neither one too prominent or convincing), we would end up with a good paper on the general aspects of psychotherapy as it is practiced by most psychiatrists the world over. If the translations are complete (which I doubt) one is impressed by the sketchy and superficial quality of the case reports. Alcoholism continues to receive a good deal of attention because it continues to be as serious a problem in the Soviet Union as it is in the Western world. The reviewer was pleasantly surprised at the inclusion of several papers on the psychotherapy of the psychoses in a country which has looked on these conditions for so many years from the strictly physiological point of view.

This book can be recommended as a good introduction for those interested in catching the flavor of Soviet psychotherapy, vintage '56, at the height of the post-Stalin thaw. It will

not substitute for the complete and unabridged translations of the current Soviet psychiatric literature.

LEGAL AND CRIMINAL PSYCHOLOGY. Edited by *Hans Toch*. (New York: Holt, Rinehart & Winston, 1961.)

This interesting and provocative symposium on law, crime and correction raises, and does not always answer, some useful questions. Mainly the work of academic and practicing psychologists, it subjects the social effectiveness of jurisprudence and justice to the observational and analytical yardsticks of psychology and, not surprisingly, finds the legal system wanting in many particulars. The flaws thus exposed are shortcomings that perennially occasion concern among advocates of social equity; they are a reflection of the unhappy contrast between sublime aims and human fallibility. As in other departments of endeavor, the imperfections of man loom all too clearly under a microscope of cold reason.

Among the indictments presented by the psychologists are these: that legislators do not make laws but merely transcribe the dictates of public pressures; that law enforcement is a selective process in which expediency and whim are principal determinants; that court procedures under the adversary system are influenced by the relative acumen of opposing counsel, by the chance trend of available testimony and by the capriciousness of juries; that judges are swayed by personal predilections and idiosyncrasies, and by unconscious prejudice; that variety in jurisdictions, in laws and in their application give justice a widely fluctuating inequity.

The authors suggest means by which some of these failings might be countered or remedied and, in some of the more intransigent areas, sensibly suggest that further effort should be exerted to attain plainly needed ameliorations and safeguards. This segment of the book is balanced with chapters by three lawyers objectively explaining the structure and mechanisms of the law in criminal and civil cases. There are also two papers by sociologists, two by correctional authorities, and one by a psychiatrist.

Although the symposium on the whole reflects the remarkable cross-pollination that has occurred in recent years between the law and psychiatry, the one psychiatric contributor, Thomas S. Szasz, who is Professor of Psychiatry at the State University of New York in

Syracuse, presents a highly critical and skeptical view of the role of psychiatry in the courts. He takes a long excursion into logistic and legalistic thinking and becomes thoroughly entangled. Challenging the forensic concept of legal irresponsibility, Dr. Szasz contends that there is no scientific justification for setting up mental illness as a category comparable with physical pathology. He dismisses the term mental illness as a metaphorical expression referring to deviations in social behavior. "The oracular pronouncements of eminent psychiatrists," he charges, "have taken the place of publicly verifiable facts." Thus, he argues, the change in court practice from the McNaghten Rule to the New Hampshire and Durham rules is "a move away from the Rule of Law toward a Rule of Man." Finding forensic psychiatry in "an apparently insoluble dilemma," Dr. Szasz would treat psychiatric testimony as only one among several types of expert testimony, with social scientists or other departments participating. He proposes that all accused persons be treated as if they were fully responsible for their actions, and that they be either fully acquitted or sentenced to jail. He would have only two types of institutions—jails and hospitals—and would eliminate involuntary hospitalization, basing the penal disposition of cases on psychiatric, sociological, ethical and other considerations. His objective is "a more consistent, candid and forthright separation of self-defined illness with self-responsibly undertaken treatment on the one hand, and other-defined 'illness' or criminality and legally imposed 'treatment' or confinement on the other hand."

It is unfortunate that instead of giving a clear-cut representation as a clinician, one gathers the impression that Dr. Szasz is a nihilist as far as mental illness is concerned. For instance, he would apparently hold fully responsible a general paretic who committed an antisocial act while in the height of delusional grandiosity. It is a rather unique view, and represents the type of clinician who tries to outdo the legal authorities, while at the same time it clouds the ideal function of a psychiatrist, which is to interpret and evaluate the mental mechanism of the accused. This is a disservice to forensic psychiatry and amateurish in its legal conception.

One deduces that this book is mainly a product of a consortium of social scientists at Michigan State University, where Hans Toch, its editor, and several of the contributors are members of the faculty. Their lively interest in forward-looking ideas in the development of forensic practice and in criminology and cor-

rection augurs well for a growing confluence of academic thinking and public administration. Two of the contributors—Robert H. Scott, Associate Director of Corrections in Michigan, and Alfred C. Schnur, former Associate Warden at Minnesota State Prison—exemplify in particular a relatively new element in the practical application of therapeutic principles to the multifarious problems of correction.

THE SENILE BRAIN. A Clinical Study. By R. S. Allison, M.D. (London: Edward Arnold; Toronto: Macmillan; Baltimore: William & Wilkins, 1962, pp. 288. \$10.00.)

This book contains a neurologist's detailed analysis of 198 patients seen and followed in his service in two Belfast general hospitals.

The word "senile" in the title is misleading as this is not a study in geriatrics. In fact only 11 of his cases were over 70 when first seen, and 25% of his patients were suffering from space-occupying intracranial lesions—brain tumors and chronic subdural haematomata. On the other hand a diagnosis of presenile dementia was made in 38 patients, which shows the value of the growing trend to provide psychiatric beds in general hospitals.

Of particular interest are the tests for disorientation and for speech and language disorders, fully described and illustrated in this book.

In discussing the development of amnesia the author points out its similarity in progression to that, seen in reverse, in recovery from traumatic and anoxic states.

This volume is a valuable review of the types of neurological and psychiatric problems seen in general hospitals.

RORSCHACH'S TEST, I. BASIC PROCESSES. Third Edition, fully revised. By Samuel J. Beck, Anne G. Beck, Eugene E. Levitt, and Herman B. Molish. (New York and London: Grune & Stratton, 1961, pp. 237. \$6.00.)

The Rorschach test has been in use for over 40 years. Originally employed exclusively by psychiatrists it has expanded both as a clinical test and as a research instrument in the study of personality, in psychodynamics, and in the field of clinical psychology.

A number of testers by now quite numerous vary greatly in their qualifications. A number of them blithely diagnose schizophrenia on the basis of the test, though they have never

seen a schizophrenic. Some psychiatrists actually employ the Rorschach testers to make psychiatric diagnoses for them.

For all the criticisms of the test it still remains, however imperfect, the most alluring of test procedures. It covers a wide range of personality variables and offers always the temptation of developing a scientific instrument of the personality as it functions in numerous intellectual and emotional capacities.

The senior author, Samuel J. Beck, has more than anyone else, as far as I know, subjected the responses of the test to the strict discipline of technique and of quantitative procedures. Testing out assumptions will still require many years of research by a large number of investigators. Beck is in the forefront of this group.

The book is replete with numerous tables. The chapter particularly on the movement response has been expanded and revised. Beck has kept this as closely as possible to Rorschach's original technique, and also to his clues in testing out a number of the original interpretations. Especially valuable are the tables of associations to the various locations on the cards and the differentiations of good and poor form perceptions.

THE MYTH OF MENTAL ILLNESS : FOUNDATIONS OF A THEORY OF PERSONAL CONDUCT. By Thomas S. Szasz. (New York : Hoeber-Harper, 1961, pp. 337. \$7.50.)

This is the quintessence of Professor Szasz's book : perhaps everybody might be himself—in his terms ; play his genuine role according to the rules (biological, social, religious, or moral) of the game. Then everybody would behave in a responsible and committed manner. However, ever so many people prefer to be (or to appear) helpless and to be helped by others. Thus they assume and/or impersonate roles. "In taking a role, then, the main task to be mastered is to put on a good performance." Transferring these premises, Professor Szasz comes to assuming that psychiatry is used "as the notion of witchcraft was used for the same purpose from the early Middle Ages until well past the Renaissance. Today we seek and achieve the denial of social, moral and personal controversies by hastily retreating into the medical game." A witch would be considered a mental patient nowadays. The professor underlines "the significance of social oppression as a determinant of the phenomena called witchcraft, hysteria, and mental illness." He uses hysteria as his example, making the best

of the hysterical inclination to and proficiency at cheating, using the role of disability and sickness. There are several side glances at mental disease in which Professor Szasz appears particularly to gauge the patient's tendency to play the game of life in a way which is not honest but does protect him.

Professor Szasz is entirely dissatisfied with psychiatry and/or psychopathology. He deplores the lack of values or rather insight into values of various kinds which are implied in human life including the life of hysterical and mentally sick people. He makes the rather sobering remark that doctors need patients, implying that without the efforts of the psychiatrists there would not be so many mental patients. He stresses that organic patients are essentially the business of the neurologists.

This book is the work of a doubtless brilliant mind. It is entertaining and interesting reading. However, it is not made evident why the "mental diseases" ought to be thrown into one pot with "hysteria." It appears to this reviewer that a goodly number of points have been known for quite a while. It damages this book that the author with a few terms of his own pretends to change psychiatry revolutionarily and fundamentally. It is regretted that he is overdoing his pronouncements. The attitude that one knows better than anybody else is not equal to the assumption of leadership in one of the "sciences of human behavior." Probably this must be so in view of the role Professor Szasz assigned to himself.

Houston, Texas.

CLINICAL JUDGMENT : A STUDY OF CLINICAL ERRORS. By Frederick C. Thorne, M.D., Ph.D. (Brandon : Journal of Clinical Psychology, 1961, pp. 165.)

The author of this small but meaty volume is qualified by education and professional training as a practitioner and polemicist in both psychiatry and clinical psychology. He is founder and editor of the *Journal of Clinical Psychology*, and much of the material in the didactic introductory chapters is drawn from his own editorials and from papers of contributors to his journal. His philosophical posture is explicitly one of empiric, pragmatic eclecticism and he exhorts his psychological and psychiatric brethren alike to recognize that their special fields can pass from undisciplined art to orderly clinical science only as medicine generally has, by proper and persistent attention to the requirements of objective observation, the rules of evidence, and the canons of logical analysis.

Approximately the first half of the book is devoted to the nature of clinical judgment, the relation of clinical judgment to diagnosis, and the particular defects of the clinician as a clinical instrument. There are ample, footnoted references to experimental studies into factors which relate to accuracy of clinical appraisal. The ubiquity and potency of personal biases and ego-involvement as sources of error in clinical appraisal are sternly delineated. These chapters provide both hygienic and heuristic reading for the psychology trainee and psychiatric resident alike.

The fact and nature of significant errors in clinical judgments of personality are documented by the presentation of 78 cases. Each case appears in a uniform format which provides brief identifying information about the "culpable" clinician, a succinct summary of the clinical case data, and a moderately detailed "operational analysis of clinical judgment error." These materials were provided by 77 clinical psychologists, the *total* number of cooperative respondents who answered a questionnaire mailed directly to 1000 clinical psychologists who subscribe to the *Journal of Clinical Psychology*. Both sexes were represented over an age range from 21-71+ years; 80% of the respondents held the Ph.D., but only 28% were diplomates of the American Board of Examiners in Professional Psychology. The years of clinical experience reported ranged from 1-30, with 40% of the respondents having at least 10 years of experience. The author remarks on the paucity of response to his invitation to professional confession "as indicative of widespread defensive attitudes on the part of clinical psychologists in admitting errors in their work." It would be instructive to know what response would be received to a similar invitation to clinical psychiatrists. The author also observes, "It is significant that the reporting of errors in the field of projective methods is conspicuous by its absence. Although projective testing represents an important area of psychological functioning and time invention, these methods were not cited, as causes of error."

This book provides exemplification of two human frailties from which the sophisticated expert on human frailty is not exempt: "To err is human"—To forget our errors more human still. Both preceptor and student can read this work with profit.

DER WAHNSINN : GESCHICHTE DER ABENDLANDISCHEN PSYCHOPATHOLOGIE. A HISTORY OF OCCIDENTAL PSYCHOPATHOLOGY. By Werner Leibbrand, and Annemarie Wetley. (Munich : Karl Albert Freiburg, 1961, pp. 698. Collection "Orbis," No. 11/12.)

This thick compilation of 700 pages contains the findings of many years of intensive research in the field of the history of psychiatry at the Munich University Institute for the History of Medicine. The authors have restricted their subject to psychopathological theories, thus providing a link between contemporary philosophical concepts and properly psychiatric developments. Six historical periods are considered : Greco-Roman Antiquity—Middle Age—Renaissance—Baroque—Enlightenment—Modern Times.

It is practically impossible to review a book of such richness. Here are a few samples chosen at random : The Pythagorians utilized a method of training which included diet, music, periods of silence and graduated exercises of memorization ; it amounted to a psychotherapeutic method (p. 20). The Stoics used another training method with written and verbal exercises of concentration and meditation, a method which centuries later was taken over by the Jesuits (p. 104). In the year 400 B.C. Antiphon erected a house near the market place in Corinth, with an inscription saying that he treated depressed people. He sought for the cause of their melancholia and eliminated it by persuasion (p. 21). In the XIIIth century the nun Hildegard of Bingen elaborated psychopathological theories reminiscent of the Freudian libido theory (p. 163). Thomas Aquinas' teaching of unity of body and soul is in concordance with modern psychosomatic theories (p. 171). The Renaissance physician, Fracastor, famous for the Latin poem in which he gave a new disease, syphilis, its name, was also the author of psychopathological theories and of a description of mental diseases (pp. 186-189). Paracelsus' intricate teaching is made intelligible if one considers that he gave two subsequent and very different theories of mental illness (pp. 206-224). The famous mystic and visionary Swedenborg was the author of a theory of brain anatomo-physiology (pp. 285-287). Stahl taught the noxious effects of the repression of emotions, which resulted in certain physical diseases (p. 321). Hoffbauer's concept of "assimilation" is somewhat akin to modern concepts of understanding mental patients and of existential analysis (pp. 385-386). Francis Willis, entrusted with treatment of the psychotic King George III,

developed a method of "moral management" which did not seem convincing to Parliament, but aroused great interest throughout Europe and became the starting point for a more humane treatment of mental patients (p. 341). J. C. Santluis, a German mental hospital director in the mid-19th century, elaborated a psychiatric system based on drives, among which the term "libido" appeared (p. 463). Leibbrand found out that current biographic notes on Pinel are webs of legend and errors (he counted no less than 21 flagrant errors in the chapter about Pinel in a well-known book!). In 1950 a student of Leibbrand's, W. Lechler, published a biographic study under his direction, the results of which are sometimes surprising (pp. 657-658). About Esquirol Leibbrand found in German archives the report by a certain W. von Mandt, who, on behalf of the German ministry, visited Esquirol in 1833. Esquirol showed him his collection of 400 skulls and 200 plaster casts of idiots and psychotics. He also had a cast of the recently unearthed skull of Héloïse. Leibbrand tried to trace this collection and found that after Esquirol's death the skulls and casts had been used as shooting targets by the hospital personnel and thus destroyed (p. 423). The authors' detailed account of Freud's sources (pp. 587-596) may be of interest to psychoanalysts, etc., etc.

Leibbrand and Wettley's book is not always easy reading, but it contains a prodigious wealth of material, the greatest part of it hitherto unknown or little known. From now on, nobody working in the field of the history of psychiatry will be able to disregard this book.

HENRI ELLENBERGER, M.D.,
Montreal, Canada.

INVESTIGATION OF CARBON DIOXIDE THERAPY.

By G. K. Yacorzynski, A. J. Atkinson, J. Cohen, and F. G. Shuffelbarger. (Springfield, Ill.: C. C. Thomas, 1962, pp. 313.)

Evaluating effects of treatment in any disturbance of mental function is difficult; it is especially difficult in patients diagnosed as having neurosis. It is not surprising, therefore, that where Meduna recommended the treatment with carbon dioxide of various disturbances of mental function, his publication was followed by those of other authors whose reports covered the routine range of improvement from zero to almost one hundred percent. As the authors of the book discussed here point out, few of the previous studies involved the use of both control subjects and blind scoring. Even those that did were unsatisfactory as

regards follow-up studies. Accordingly, the present work is a welcome change.

The study was based on 39 patients with neurotic complaints that included those of irritable colon. Approximately 50% were given 60 carbon-dioxide treatments and the rest received similar treatments with nitrous oxide. A vast number of psychologic variables were tested before and at intervals after the treatments had been terminated.

Two things are evident in this study: 1. That psychiatric evaluations often indicated more improvement than did psychologic studies, and 2. That both experimental and control patients improved approximately equally, the improvement perhaps occurring somewhat more rapidly in the patients who received carbon dioxide than in those who were given nitrous oxide.

This report is one of the best available studies of the effects of treatment in neurosis.

Waverley, Mass.

SERVICES FOR CHILDREN WITH EMOTIONAL DISTURBANCES. Prepared by *Committee on Child Health of the American Public Health Association, Inc.* (American Public Health Association, Inc., 1961, pp. 120. \$2.50.)

This is a valuable guide for public health personnel including community leaders dealing with emotionally disturbed children. An attempt is made to identify what is known and to locate gaps in knowledge. Central issues are presented, new trends explored, and all in all the material compactly presented provides a reasonable summation of present knowledge. The many excellent contributors hope this knowledge will promote comprehensive physical, mental and social health and improve community care of children with special problems. It should.

The range of topics is impressive ranging from concepts and facts about emotionally disturbed children, causes, prevention, case finding and treatment to special services and facilities, professional personnel, organization of community resources and trends in research. There are valuable appendices about official and voluntary agencies, vocabulary of mental health terms, and a selected bibliography. It is clearly and readably written and avoids confusing terminology. While not primarily designed for psychiatrists, it is well worth their while if they deal with the community. All disciplines can find much of value in this paper bound book.

U.S.C. School of Medicine.

FATIGUE, REST AND EXERCISE^{1, 2}TREVOR OWEN, M.B., F.R.C.P. (LOND.), F.R.C.P.(C.)³

If a single living muscle is excised and stimulated by an electric current it can be made to contract. If the stimulation is repeated often enough the contractions will become more and more feeble and finally cease. The muscle is said to be fatigued. The energy for contraction was supplied by the conversion of glycogen into lactic acid. The complete fatigue is due to the fact that the hydrogen-ion concentration has risen to such a point that no more glycogen can be converted into lactic acid. During rest, with an adequate supply of oxygen, sugar, and bases to replenish the alkali reserve, the lactic acid is reconverted into glycogen and recovery is soon complete. No analogous production of complete muscle fatigue ever occurs in the human being and yet the symptom of fatigue is often considered and treated in the light of this simple experiment. An additional factor is often postulated, namely, that the blood supply is inadequate in that it may contain some toxic agent, as in hyperthyroidism or be deficient qualitatively, as in pernicious anaemia. Often that is true.

If we stimulate the excised muscle by way of its nerve in the same fashion, we find that the same phenomenon occurs, namely, that after a few stimulations the muscle will stop contracting. However, if we at once change the stimulation from the nerve to the muscle, the muscle will again contract and continues until entirely fatigued. This shows that the nerve fibres fatigued before the muscle. If, in a third instance, the stimulus for muscle contraction is done by the mind through the nerve path to the muscle, we find that the subject

of the experiment is able to keep up voluntary contraction of the muscle to a point at which he describes complete fatigue. He means that he is unable to make a voluntary effort of *will* sufficiently strong to contract the muscle. If, at this moment, the nerve supplying that muscle is then stimulated, the muscle will contract until the nerve fibres are exhausted and immediately further stimulation of the muscle will show response to stimulation to a further point. Thus, the onset of fatigue is earliest in the mind, next in the nerve fibres themselves and finally in the muscle. We see, therefore, that the contraction of a muscle, *i.e.*, a certain form of energy production or behaviour is limited by the ability of the subject to bear the cerebral distress of making an effort of *will* against increasingly strong, disagreeable painful sensory impulses. This is normal functional fatigue. Obviously, the quantity and quality of the blood to the parts must be adequate. A poorer quality of the blood, either from a deficient supply of normal materials as in heart failure or in deficiencies such as myxoedema, or because of the addition of toxic materials, as in active tuberculosis, will greatly reduce the time required to produce the syndrome called fatigue. This is organic fatigue.

Normal functional fatigue can properly be designated as the sensation and general experience and behaviour of the athlete after physical endeavour. This might be called "athletic fatigue" and can apply to ordinary fatigue or to fatigue in average persons who have only relative perfection of the integration of function, the perfection of integration of function coming only with athletic training. The state of the perfection depends on the life led by the individual.

In extreme athletic fatigue, one sees the fatigue of the mind, nerve paths, muscles, *etc.* It is impossible to say what part fails first, because the whole organization breaks down together and the point at which it breaks down is called the maximum produc-

¹ This is the successful Myers Memorial Essay for 1941.

² This paper was printed originally in *The Canadian Medical Association Journal*, 47 : 41, 1942. Permission has been granted for its reprinting here.

³ Graduate Lecturer in Medicine, University of Toronto.

tion of energy of which that individual is capable. It is the purpose of an athlete's training to build up the efficiency of the various systems individually and also co-operatively. This perfects integration of chemical and physical functions and implies the proper inhibition of unimportant activities. Final physical exhaustion is reached when the cerebral distress from peripheral stimuli becomes so great that the individual is unable to initiate any voluntary effort further. Athletic training, therefore, enables, first, the best possible integration of all physical and chemical processes in the various systems so as to delay the onset of extreme discomfort, and, finally, the training of the mind to stand increasing discomfort up to the final point which we call the "capacity" of that individual. This is not to say that weakening of the mind is the limiting factor in the full psychomotor power, but that that particular individual has reached the limit of his mental strength at that degree of disagreeable, sensory bombardment due to the increasing hydrogen-ion concentration and his diminishing supplies of raw materials, sugar and various salts. Thus, the mind is the first threshold of fatigue. As the pace and the time increase, the sensory barrage reaches and finally breaks the *will* of that person in order to save him from a disintegration of function and structural damage.

ORGANIC FATIGUE

The fatigue in organic disease is presumably caused by toxæmia. In addition to the diseased tissues involved in energy production, toxic agents alter cellular chemical processes, producing inadequacy in the signalling mechanism from faulty hormones or disordered function of the autonomic nervous system. The fatigue is not necessarily present until the tissues are being used and is thus in some respects comparable to that felt by an athlete approaching the limit of his capacity. The discomfort will be slightly different, however, since particular toxins will often have a particular selective effect. For instance, it may have its maximum effect on muscle fibre or on nerve tissue or on the liver or on the brain cells, though all tissues will be affected. The fatigue of organic disease is banished to more

or less an extent by inactivity and increases with activity and is felt later in the day. Organic fatigue is an efferent difficulty, that is to say, there is resistance to motor stimuli, probably at the neuromuscular junctions. At the same time, there is increased afferent facility with heightened irritability of sensory stimuli. This decreasing resistance to sensory stimuli brings about cerebral distress earlier and has a biological object in the preservation of the individual. The break in the continuity of the production of energy begins peripherally, but the continual perception of uncomfortable stimuli finally fatigues the mind and the patient becomes irritable, depressed, and shows a diminution in his powers of concentration. Inactivity, *i.e.*, rest, by reducing the number of peripheral stimuli will allow these effects to pass off. But the constant repetition will finally induce what we call "habit" and this occurs on the afferent as well as the efferent side. Once a habit has been induced, the imprint remains for ever, growing fainter with the passage of time. Any future fatigue, whether organic or functional, may reveal those imprints in that habit pathway or pattern. Thus the previous habit of pain from the region of previous inflammation or other disease may appear in an episode of functional fatigue. The pain of duodenal ulcer from muscular spasm there may reappear when that individual is functionally fatigued from psychological causes, a habit of reflex spasm having been established when actual ulceration was present on former occasions. Now, without the ulceration, but merely because of the facility of afferent and efferent stimuli in that area, the fatigue phenomena are increased during normal usage of that part. Constant or repeated perception of afferent impulses increases the acuteness and skill of recognition of those impulses and the shades of quality changes in those afferent impulses increase enormously with the practice of that appreciation.

FUNCTIONAL FATIGUE

Functional fatigue begins centrally and extends peripherally. It is made worse by inactivity (rest) and is therefore most severely felt in the early part of the day and wears off as effort is made by deliberate

action or necessity. The effort of *will* to initiate an effort of a physical or mental kind is great. The great inhibiting influence is a lack of desire or wish to initiate an effort.

In 1935 Norman Johnson in *Minnesota Medicine* (Vol. 18, page 531) published an excellent article on "Non-organic Causes of Fatigue" from which I freely quote. He quotes Capt. Hadfield of the British Army, "In the production of energy we are motivated by two forces. First by *impulse* (or desire) which is the stronger, and secondly by the *will*. Man gets his superhuman strength when his instinct or impulse violently urges some policy and his *will* gives complete and unqualified approval." When this is the case, no fatigue sets in, except the athletic exhaustion above referred to. Postponement of the cessation of energy production can be brought about by adding the nerve stimulation in order to augment the *will* power by some sort of suggestion. This is frequently used, such as the exhortations of the cox in the rowing crew, the cheering of a crowd for encouragement or by using some rhythmical, musical stimulation as in the dance and the army band. Conversely, earlier exhaustion, or a diminishing of the ability to stand the cerebral distress and exercise or "complete and utter fatigue is brought about when impulse or instinct strongly dictates a policy and the *will* violently disapproves." This is conflict. "In emergencies, one's reasoning powers move too slowly, and most of us revert to instinctive reactions of fear, anger, hate, jealousy, pride, greed, worry, anxiety, disappointment, self-consciousness, self-pity, despair, etc." These have tremendous powers for inhibiting our automatic machinery and bringing on fatigue symptoms. The subtle influences of fear in all its forms and grades are not easily analyzed. "The important point to remember is that our machinery is geared directly to our emotions." As mentioned above, superhuman energy is seen in action when our emotions coincide with our will. Where these are not in strict harmony, functional fatigue sets in to thwart the object of the weaker one. For example, "a person has functional fatigue when he forces himself to perform some task which he heartily dislikes, where-

as five times the energy is expended on some pleasant task which results in only transitory fatigue" (Hadfield) of a different kind. "Some persons have been educated to put an emphasis on results, rather than giving their best effort to the performance and to let the result happen. If the best is done, automatically you will produce the best result of which you are capable. Work should be done without getting mentally in a hurry."

"Functional fatigue is also caused by the refusal to accept an adverse fact. Most basic of all is probably the fallacy of the conviction of our individual entity being the centre around which all the rest of the world revolves. This produces 90 per cent of the disagreeable emotional upheavals of an individual and of mankind. The most enjoyable experiences have come at a time when one's attention was riveted on some consuming interest, on some goal for which you strive, or in fact anything except your relative position in life." The symptoms of functional fatigue are due to the inco-ordination between the various systems and the imbalance between the sympathetic and the parasympathetic portions of the autonomic nervous system. When slight, the actual biochemical changes are not measurable by our methods and yet some of the biochemical changes with emotion are known. When functional fatigue is chronic and more severe, biochemical changes are demonstrable; changes in the basal metabolic rate, changes in the sugar metabolism, changes in the blood pressure, changes in the pulse rate, and also changes in the heat control mechanism. Thus in severe functional disturbances, some of these changes in metabolic processes may be severe and be mistaken for the changes often seen in organic disease. Even in mild psychoneurotics, earnest attempts are made by medication or surgical therapy to rectify these changes in function without success. This lack of success is inevitable because these changes are the effect and not the causes of the disturbance. Frequently, the measures taken to alter these effects merely cause further upsets in function, together with the functional upset that comes from chronic disappointment. Most commonly, the disorganization which brings on func-

tional fatigue and due to disorders of the autonomic machinery is an acquired state and can easily be mistaken for organic fatigue. Psychological causes such as boredom, disuse, lack of discipline, and chronic fear connected with the social state, with the economic state and with physical health are common. The neurasthenic is a personality who has a poorly functioning nervous system from birth and these are the people who always have suffered from an uncomfortable functioning of their bodily machinery brought out more easily and more violently under conditions of stress and strain, that is, when they attempt automatically to adjust to some change in the environment which is too great for them. These are the patients who are always complaining; that is to say, they always have symptoms.

An important group of patients in whom functional fatigue is of particular interest are those who have inherent defects of vegetative function. These are the migraine personalities with its various equivalents such as asthma, eczema, angioneurotic oedema, urticaria, mucous colitis, cyclic vomiting of children, and certain types of dysmenorrhoea. Functional fatigue, manifesting itself always through disturbed vegetative function, will of necessity bring these defects out in high relief and the appreciation and treatment of the additional psychogenic factors are fundamental.

REST AND EXERCISE

Rest from athletic fatigue means the total inactivity of the body and mind for a period which has definite limits. In organic fatigue, namely, that due to toxic states due to infection, degeneration, or new growth, or to poisoning from endogenous sources, rest is also that of an inactivity of the part and of the whole patient until the source of the intoxicating material is removed and the results of the intoxication are repaired and the metabolism of the cells is restored to normal. As soon as the toxins are removed or prevented from forming, the convalescent state begins. This rehabilitation period, called the convalescent state, is a period of change and requires a nice adjustment between rest and increasing exercise of the part and the whole of the patient. The fact

that the whole individual is taking part in the convalescence is often overlooked. Graduated use of the various faculties and physical properties of that individual have to be used in greater frequency and in increasing difficulty. This is analogous to the early part of an athlete's training. During the convalescent stage from infection or other toxæmias, many of the psychoneurotic states originate in healthy people. The previous toxic state has resulted in a disintegration of function of the various systems and of the cells in each system and, following the removal of that toxæmia, *this* functional fatigue remains. The restoration of this liability to functional fatigue may well be met with the ordinary natural tendency of the individual to recover spontaneously. But, if the period of previous toxæmia has been prolonged, even those who have strong autonomic nervous systems and constitutional organization, as it is called, may yet require careful coaching in the re-education or exercise process to avoid the habitual functional fatigue symptoms which are necessarily and normally present at the beginning of the convalescent stage. It can thus be seen, too, that in long continued, chronic, organic disease and in suitable personalities, functional fatigue symptoms overtake and overshadow finally the organic symptoms. Frequently, however, the distinction between the organic symptoms and the functional fatigue symptoms is not clearly distinguished by those who come in contact with the patient. Therefore, there is a possibility that the whole complex clinical picture becomes a mixture of functional, that is to say secondary psychoneurotic, symptoms combined with the organic symptoms and the latter may fade in reality to the vanishing point. The onus having started with the organic disease, symptoms may still be thought to be treatable on the basis of the original organic lesion, but specific treatment directed towards the organic lesion will not, of course, have any effect on the secondary and now more urgent and possibly overwhelming symptoms of functional nervous disturbance.

The word "rest" is used rightly when applied to the fatigue of organic disease. Inactivity, however, is not restful for the organization that is suffering from function-

al fatigue, and becomes but an opportunity for deterioration. In functional nervous disorders, rest is only obtained by using all parts, including the mind and nervous system of the organism in the way that they were supposed to be used, beginning with a small amount and increasing the difficulty and the duration until a normal level of usage is arrived at. Together with this, frequent changes in the kind of energy production is the only way of producing a restful effect. Anxiety or fear and boredom (monotony) are the greatest producers of functional fatigue. The only method possible to remove fear and boredom is, first of all, that the patient and the doctor should be aware of their presence, to accept their positive reality and be willing to try to erase them. This sets in motion psychological and physiological constructive forces which are inherent in each individual. They are, of course, strongest in those who are endowed with a strong intellect and intelligence. The physiological benefits from clear understanding are enormous. Rest, therefore, consists of an alternation of activity with shortening periods of inactivity. Exercise is the initiation of different kinds of effort. This practice in *willing*, in the presence of understanding, does increase the strength of *will power*. The rapidity of recovery, therefore, depends mostly upon the previous habits of discipline in that patient.

Exercise consists in the repeated trials of the efficiency of the integration of that individual at the moment, the test requiring a more perfect integration than obtains at that time and, therefore, resulting in slight sensations of fatigue. This process of working the organization just beyond its level of efficient integration at the moment and giving rise to a suggestion of increased effort, whether mental or physical, is what we call education. By the repetition of this procedure in health, a greater production of energy will be found possible before inefficient integration takes place, with the important proviso that the experiments should not be too far apart. This is best illustrated by the athletic illustration, namely, that in running a race of say, ten miles, the first effort should be half a mile, the second three-quarters of a mile, the third one mile, the fourth one and a half miles,

etc., but the intervals between these extensions of time and distance will have to be carefully selected, for if the interval is too great the previous education involved in increasing the distance will have worn away. The word education has usually been applied to intellectual activities alone but the same principle holds good. Exercise also consists in the practice of varying co-ordination, as it is just as important to have perfect inhibitions as it is to have perfect stimulation.

The previous discipline of the patient in every sphere is seen frequently in organic disease. The more disciplined the patient has been previously, the longer will be delayed and the less severe and elaborate may be the symptoms of the onset of organic fatigue. In this way more severe toxæmias, especially if started slowly, will be borne by the more disciplined patient. In them toxæmia may reach a high point before the patient will acknowledge fatigue. On the contrary, the undisciplined, emotionally uneducated patient has symptoms of fatigue from a slight organic lesion. He has been educated in easy disorganization.

Many somatic discomforts and signs are expressed by the word "fatigue" and those of functional are no less important than those of organic origin. Of the functional variety there are those due to abnormalities of vegetative function from mildly pathological psychological states—the commonest of which are fear and dissatisfaction. My concern here is to re-emphasize the truth that organic dysfunction, functional vegetative dysfunction, and psychogenic dysfunction are all on the same physiological footing and must be dealt with by the physiological method. They all give rise to symptoms difficult of distinction. The simple psychological analysis of an ill individual is not *more* important than the organic analysis—the point is that it is not *less* important. Its omission is unscientific and represents one of the serious flaws in the practice of the art of medicine today, particularly by specialists. Literally, hundreds of years of good health are lost by not taking time to do this. The natural history of the patient; as he has been born, as he has been reared and fed, as he has been acted upon by people's opinions, as he has been affected

by religious, social and economic conditions, is equally important (neither more nor less) as the effect on him of pathogenic organisms or of degenerative changes in his tissue cells. Take nothing for granted. The absence of significant findings is quite as helpful as their presence and therefore our duty compels us to examine the private life and

thoughts of patients just as carefully as we should do a rectal examination. Medically, one is not more private than the other.

Not until the organic or non-organic nature of fatigue symptoms are appreciated can the appropriate measures of correct rest or exercise be applied with understanding and wisdom.

LOBOTOMY IN WESTERN PENNSYLVANIA : LOOKING BACKWARD OVER TEN YEARS¹

ROBERT L. VOSBURG, M.D.

Nearly a quarter century ago a frontal attack was launched quite literally against mental illness. Indeed, at one period in its history, prefrontal lobotomy or "psychosurgery" was hailed as a new era in psychiatric therapy.²

Enthusiasm for prefrontal lobotomy in Western Pennsylvania mirrored national practice, as between 1944 and 1957, 229 operations were performed by neurosurgeons for treatment of mental illness. In 1949, the operation reached peak frequency locally when 55 patients were treated.

This survey was made in order to find out what changes took place in this group of severely ill psychiatric patients. When preparations for the job of follow-up were being made, it became evident that local medical opinions about the effects of lobotomy were conflicting and that acrimonious debate characterized much of the literature regarding this procedure. Despite the scholarly monographs of Freeman and Watts(1) and other enthusiastic supporters of surgical treatment of mental illness, it was evident that diverse procedures of selection, operation and evaluation led to quite different overall results and sentiments.

Freeman, for example, reported that over 80% of 500 patients who were followed over 20 years were discharged or gainfully employed(6). Paul reported similar "favorable results" with 65% of his patients(7). The largest series was reported by Tooth and Newton who observed that 46% of 10,365

leucotomy patients in England and Wales had been discharged after 10 years and that at least 40% were much improved(20). On the other hand, while this survey was being carried out Barahal reported the 10-year results of 1095 lobotomized state hospitalized patients with a discharge rate of 21% (8). This figure corresponds to the discharge rate reported in this study and, even more significantly, to the discharge rates of a similar, untreated hospital population reported by Hastings in the same year(9), and to the generally negative, if always precise, findings of the Columbia Greystone project associates (2; but see 10).

The explanation of these differences has been the topic of research seminars(3-5), annual reviews of the literature by Freeman, and extended reviews by Kolb(11), Greenblatt(12), Tow(13), and Freeman (14).

Illustrative of the differences of opinion are the following excerpts: Greenblatt writes that all lobotomy reports are characterized by an "astonishing similarity of results," while Tow writes "what emerges most obviously from this review is the great variation in results and the clinical opinion as to their interpretation." He adds, "This is not surprising in view of the wide variation in material."

It also became evident in our early preparations that the old hospital charts often omitted what seemed like vital data, that valuable psychological test records had become misplaced, and that no strict, precise before and after measures would be available to us to settle any debates. In view of these limitations reliance was placed on two simple methods, a straightforward clinical interview of the patients who could be reached and a simple tabulation of the current treatment status of all patients.

Procedure. Two hundred and twenty-nine patients were selected who had been lobotomized from 1944 to 1957 (Graph 1). As it happened 104 patients were selected, treated and followed by the Western State

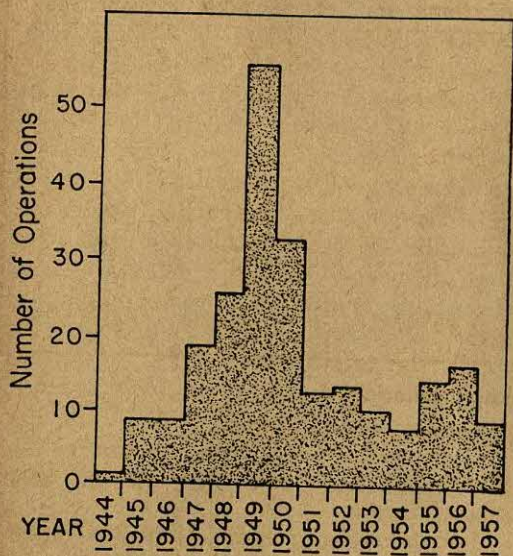

¹ Read at the 118th annual meeting of The American Psychiatric Association, Toronto, Canada, May 7-11, 1962.

This project was directed by Henry W. Brosin, M.D., Director of the Western Psychiatric Institute and Clinic. Statistics were compiled by Mrs. Edith Fleming of this staff. Yale D. Koskoff, M.D., not only performed most of the surgery but also was a helpful critic during each stage of this survey.

² "This volume inaugurates a new era in the treatment of mental disorders, a surgical era . . . (It) reveals how personality can be cut to measure, sounding a note of hope for those who are afflicted with insanity." From the book jacket of Freeman and Watts, *Psychosurgery*(1).

Performed in Western Pennsylvania,
by Year, 1944-1957.

Psychiatric Institute,³ and 125 patients were selected, treated and followed by other hospitals in the Pittsburgh area. The hospital chart of each of the 229 cases was examined and a tabulation made of the ratings "improved," "easier to care for," or "unimproved" (or their equivalent terms). Discharge status was noted and tabulated.

Detailed case history data were collected from all patients who were eventually discharged from the W.P.I.C. portion (*i.e.*, 17 of 104) and all the lobotomized patients at a nearby state hospital (*i.e.*, 15 of 229). This selection was dictated by convenience and reason. The charting procedures at W.P.I.C., as well as the personnel who wrote the notes, were familiar: this lent a conviction to the comparison with present impressions that would have been totally lacking otherwise.

Controls. The results of the W.P.I.C. group (104) are controlled by the remainder (125) for the effects of selection and treatment at one institution.

To compare the outcome of lobotomized

persons with unlobotomized patients, over 700 charts were searched, using the criteria "lobotomy recommended but not carried out." Unfortunately, this search yielded only a handful of cases.

At the time of operation, 95% of the 229 patients were chronically hospitalized psychotics. Lobotomy was frequently characterized as "the last resort," although the operation was withheld from many because the expectation of success seemed so meager. This kind of population has been characterized by Whitehorn as "prolonged and unsatisfactorily responsive depressives and prolonged and unsatisfactorily responsive schizophrenics" (3).

All of the operations recorded were bilateral lobotomies performed under direct vision through trephine openings.

Results. 1. Overview: At the time of follow-up in 1958, 43 (19%) of the 229 patients had been discharged, 162 (71%) remained hospitalized and 24 (10%) had died. Ninety-four (58%) of those now in hospitals are considered "improved" or "easier to care for" (Chart 1).

The discharge rate and improvement ratings for the patients treated at the W.P.I.C. and the patients treated at other hospitals were similar on all counts.

The fractions of "improved" cases and "easier care" cases stabilized within 5 years so that the expectation of some symptomatic improvement from lobotomy could be held for 4 of each 10 patients (Graph 2).

The recovery ratings did not correspond closely with clinical diagnosis, sex of the patient, nor prognostications (when these could be traced). Other variables, such as length of hospitalization, mode of symptom onset, social class, education, and marital status, were not compared with the results. The patients ranging in age from 30 to 50 fared better than either younger or older patients. The significance of this is by no means clear; it is a fact that these groups were considered less desirable candidates for the procedure, and so those who did receive lobotomy may have been sicker on the whole than those patients in the middle group.

After 1957, 6 lobotomies are known to have been performed locally. Three patients were outpatients. One, markedly

³ The name was changed in 1949 to Western Psychiatric Institute and Clinic when a reorganization took place.

Chart 1

phobic, achieved striking relief; two others, each with somatic complaints, were un-

changed or worse. The inpatients were unchanged.

Graph 2

Improvement Ratings Expressed as Per cent, by Year

Lobotomy has steadily diminished in frequency; this is due to the low expectation of real success, the unpredictability of results and the advent and availability of the tranquilizing drugs (Graphs 3, 4).

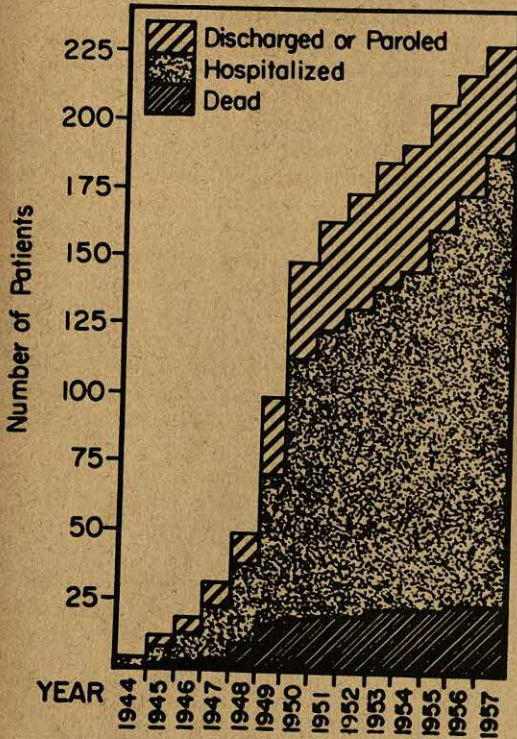

2. Clinical findings: Four of the 17 patients discharged from the W.P.I.C. group seem to feel happier, are able to work more consistently, and are certainly less destructive than they had been for many years. This is to say they are cured, according to clinical standards. The remaining 13 although discharged show a variety of symptoms ranging from overt psychosis and vegetative existence to persistence and even exacerbation of functional complaints and obsessional rumination.

Illustrative Case Histories.

1. Edward M. failed in his business at the age of 36 and developed a suicidal depression with paranoid preoccupations; these symptoms continued for 10 years. Thirteen years ago he received lobotomy. Now he is a pleasant submissive man who works steadily as a stock boy in a music store. He remarks that his tendency to worry is gone. He feels that his memory is excellent, but he no longer enjoys reading because "it's difficult to concentrate." He lives comfortably with his sister (he never married) "who has always been like a mother to me." He

Status, by Year

tended to avoid and to deny or project unpleasant issues.

Comment: In some studies this kind of result is evidently common: Greenblatt, for example, characterizes the lobotomized personality as showing a reduction of drive, lessened self concern, greater social accessibility and some shallowness (12). As will be seen this generalization is not applicable to all.

2. Nan A., as a girl, had been timid and depressed. Although she married her childhood sweetheart they were childless and she fell into deep despair. Lobotomy was given at age 32 to relieve excruciating headaches and suicidal preoccupation. Following lobotomy 8 years ago she became outspoken and energetic. She began to ask for sexual relations with her husband. After 14 years of marriage, 3 years after lobotomy, she conceived and bore a son. Her husband professed to be pleased. Unfortunately he suffered two coronary occlusions, the first coinciding with her return from the hospital

and the second in their child's infancy. He died with the second attack. She became a diligent and loving mother, assisted in great measures by her sister and brother-in-law, a childless couple living nearby. Over the years the excruciating headaches have returned and at the time of follow-up she was noted to have an alarming hypertension (290/150 R.A.S.).

Comment: It is noteworthy this woman's headaches have returned and that she has developed essential hypertension. Apropos the family, Koskoff and Weniger had observed that oftentimes the recovery of one member has disastrous effects upon the other family members (15). While this dramatic example supports their observations, it was atypical. The patient's recovery, on the other hand, was abetted by the continuing support from her childless sister.

3. John D. had been a conscientious hard-working young man. Following an injury at work he was involved in a lawsuit for which he eventually recovered a small settlement. He became fearful that people were "out to get

him," and developed a paranoid panic. Following lobotomy 11 years ago the intense agitation ceased. He returned to his mother and has never shown any more interest in his wife. Nor has he worked consistently. He has been a constant clinic visitor. When interviewed he was preoccupied with somatic complaints, tangential in his talk, and became furious. He said, "I feel no better; I'm like the weather; if the day is nice, I'm tops . . . They made a goddamn fool out of me!"

Comment: This kind of psychotic, blow hot and cold personality suggests other stereotypes attributed to lobotomy. Many medical people, it was found in this survey, tend to think that lobotomy produces a sub-human who is "fat, sloppy and promiscuous." Looking back to other characterizations, this story probably starts with Phineas Gage, the hard working and reliable gang foreman who became a cursing drunkard after he survived a crowbar through his brain(1).

4. Paul J. was a quiet seclusive youngster. As he grew older he took up with a "gang," started to steal and to show interest in women, which disturbed his mother. He began to fear that some neighbor would molest his sister. He became openly psychotic and critical of his mother and family, and smashed some furniture. He was careless and incontinent when hospitalized and unable to cooperate with psychological testing. In 1946 lobotomy was done at age 29. He has not spoken since that time. He lives with his mother who insists on taking complete care of him. She feeds him and changes his clothes. He watches television. His mother remarked, "While he didn't do the way the doctors promised, he's manageable, and has no pain, and he's a good boy." He is uncommunicative except for grunts; he is incontinent of urine and feces.

Comment: This case illustrates how little relationship there may be between discharge and "recovery."

5. Maria C. was, and is, a constant source of psychiatric interest. She began therapy with a psychoanalyst, Dr. S., in 1944, but broke off. She was hospitalized at the Menninger Clinic for "incapacitatingly severe headache, nausea, insomnia, terrifying dreams, fear of dirt, and crawling things, feelings of hatred and hostility, and the inability to look at pictures or to read," diagnosed "schizophrenic" and referred to W.P.I.C.

She was admitted in 1946 and saw 6 therapists before her discharge in 1949. With each therapist, there was initial progress, relief of symptoms, then withdrawal from therapy with symptoms similar to the original breakdown.

During her hospitalization ICT, ECT, narcosynthesis, and CO₂ were administered. Lobotomy in 1949 was the last definitive procedure. Shortly postoperatively she was moved to a nearby state hospital from which she was discharged. She has been seen intermittently by psychiatrists since and followed the same emotional pattern as observed before. She has responded to all treatment as love affairs; initially she would be pleased, then become anxious, and finally become enraged and depressed. She was enamored of her physician at the time of the operation and sees the lobotomy as a loss, particularly of memory for music and dreams. Lobotomy has even taken on some of the aura of a sadistic attack ("I wouldn't let them do it to a dog").

The most noticeable change in her activities is the conversion to Jehovah's Witnesses from the Greek Catholic Church, a change observed in another case in this series as well.

The family does little to support her, but does provide food and shelter. They are openly antagonistic toward her.

Comment: This complex person has not been helped by lobotomy. But more important, it is possible to assess some of the effects of the operation relevant to psychotherapy. Her transference pattern seems to remain unchanged. The perseverance of compulsive behavior was also striking; she now uses 7 wash cloths to bathe, one for each part of her body, where previously 3 had sufficed. The change in religious affiliation could be interpreted as a consequence of a personality shift toward outgoing traits (on the basis that Protestant, evangelical sects are more "emotional" than Catholic traditional sects)(16, 17). This change might also be interpreted as seeking salvation from a hitherto unexhausted social resource. The second explanation implies less impoverishment of ego than the first. There was much in the history to suggest that this woman brought about surgery by masochistic manipulations; possibly her present depreciation of lobotomy indicates no more than depreciatory attitudes toward men. In any event, the striking clinical fact is the persistence of her suffering behavior unmitigated by psychosurgery.

6. (Permanently hospitalized.) Joe S. was a truculent boy and quarrelsome young man. He was unable to hold a job and gradually became involved in more fights and became unintelligible. He received lobotomy at age 27, 9 years ago. After the operation he seemed to be similar to his earlier self. He has remained a state hospital patient. There he functions well on a work gang, swearing and cursing continually but going largely unnoticed by his fellow workers. In the interview he was quiet and seemed frightened and showed meticulous mannerisms. He said, "The medical treatment was perfect . . . never had an operation. A pigeon was run over by a truck and had its head chopped off."

Comment: Joe S. appears to feel that he has been castrated, in the psychoanalytic meaning of the term, as did 6 other patients. The allusions to castration were less veiled in the hospitalized group than the non-hospitalized group. Similarly the manner of denial was more gross in the hospitalized group.

Seven of the patients interviewed made unmistakable allusions to the feeling that they had been damaged. This fear is, of course, widespread. Whether it is "fixed" by the actual event of lobotomy is worth consideration.

7. (Chronically hospitalized.) Lilly M. received a lobotomy at age 47, 9 years ago, a fact that was greeted with surprise by the ward personnel at follow-up. She is presently loud, oafish, and sexually promiscuous. She works in the laundry. She is noted for rapid shifts from religious preoccupation to hostile profanity. Generally she is disliked by the patients.

In the interview she commented that, "I think it was a wonderful operation. It got rid of the fear. It changed my entire attitude. I'm kinder, more lenient, and try to be good. My memory has improved. After the operation a voice said, 'You are forgiven.'"

Comment: The clinical picture of the lobotomy patient who remains hospitalized is highly variable. Many were less combative postoperatively but several could be controlled only with large doses of Thorazine. Lilly M. denies the impact of lobotomy and her opinion of herself corresponds not at all to the opinions held of her by others. The patient's remark, "You are forgiven," raises a familiar but moot issue, the

problem of how guilt is modified by various therapies and to what extent behavior after treatment represents propitiation of the physician.

Summary of Clinical Findings. The findings from this survey indicate that the changes following lobotomy include impaired memory, diminished adult sexual contacts, some increase in somatic symptoms and complaints, a change in attitude towards one's self, increased repression and suppression of reflective thought and increased extra-punitiveness. These people tend to withdraw more, yet to be more outspoken and critical than previously. In sum, they act as if they have been hurt.

The incidence of psychosomatic illness seemed striking. Progressive arthritis, ulcerative colitis, migraine and weight fluctuation were observed. Prior notions that the loss of frontal lobes might obviate psychosomatic illness proved false. It was impossible to obtain detailed histories of sexual behavior; it seemed that most of the patients had diminished sexual interest. Masturbatory activity was not remarkable, according to ward personnel.

In all of the patients the residual of their psychosis remained, as Freeman observed 20 years ago(1). For some it was a recurrent dream that required constant suppression, while others dealt with irrational thoughts by constant projection and denial. All in all these patients seem to worry less, to be more concrete, and to be less in pain than preoperatively.

DISCUSSION

Among reports on lobotomy "the great variation in results and the clinical opinion as to their interpretation" is attributable to differences in selection procedures (14, 18, 19), and to an over-estimation of the role of the frontal lobes in the behaviors called personality and mental illness.

Our data indicate that prefrontal lobotomy is regularly followed by a time of readjustment to the social system extending about a year. Typically compensatory constrictive and regressive defenses develop. Whether the induced brain syndrome comes to be recorded as "improvement" or not depends upon the niche available to the postoperative patient. Sustained recovery is

a reading on the equilibrium struck by the social environment and the patient. Without some modification of the external environment, old symptoms and old acclimations recur.

Because physicians in the 1930's and 1940's generally believed that the higher mental processes were localized within the frontal lobes, the potential consequences of lobotomy loomed disproportionately large. Therapy was conceived as either selective ablation of the bad parts or successive strengthening of the good parts. Surgeons sought to do the former, psychoanalysts the latter, and the division of opinion followed these lines. But it turned out that ablation of the frontal cortex did little to change the balance between good and bad within individuals. Psychological test measures, formerly regarded as accurate indices of brain damage and mental illness, were found to be inadequate to the task of definitive diagnosis and evaluation. This finding, once accepted, led to careful re-examination of old assumptions and increasing sophistication of research design, and to the development of new test batteries.

Prefrontal lobotomy constitutes two things, damage to the central nervous system and a dramatic event in a life history. Each has its own consequences and neither is necessarily closely linked with the other. The changes due to tissue destruction are subtle and difficult to measure. The changes due to significance are characteristic of all symbolically charged events. To many patients and their families, especially in the early years, lobotomy meant special recognition and special status. This was sometimes enough to reorganize the family. Other patients, we may gather, were so much needed by their families that minor deficiencies attributable to brain damage could be easily tolerated. Chronic state hospital patients, on the other hand, had been generally written off as liabilities by their families. Curiously, many physicians came to characterize lobotomy patients as "fat, sloppy and promiscuous." The explanation for this erroneous judgment must be sought in the fears of the observers and the behavior of a few patients, for it is not supported by general findings of obesity,

carelessness, or promiscuity. Similarly the feeling commonly expressed by lobotomy patients that they have been mutilated may be interpreted as a reconstruction of their life history according to a dramatic event, psychic rather than physical reality. All histories, as well as follow-up studies, must be interpreted within the climate of opinion of their times.

A NEW TYPE PSYCHIATRIC RESEARCH WARD

GEORGE SIMPSON, M.B., CH.B., AND NATHAN S. KLINE, M.D.¹

The weakest point in the entire edifice of psychiatric research is the very cornerstone upon which all the other components must rest—the systematic observation of the patient. Biochemical, physiological, psychological (in the limited sense) and even sociological activity can be measured, but we lack a satisfactory method of describing “overall” behavior in a quantifiable manner.

Interviews with patients suffer from the limitation that they are necessarily of relatively short duration and restrict the person being interviewed to a situation which may not reveal important aspects of behavior.

The use of attendants and nurses as raters usually produces ambiguous data since such service personnel are constantly interacting with the patient in the line of duty and since usually the patient either assists or impedes the performance of these duties, the rating itself cannot be entirely objective. In certain situations such reactions and opinions of a participant observer may be useful but there are other times when an objectivity is claimed for this type of observation which it does not actually possess.

Not only the observer but the usual physical setting produces problems. Attempts to record data in a hospital day room are difficult because of the large size of such rooms and the consequent number of patients. On the other hand, observation in an isolation room or in a small space with one or two other persons is not a “natural” environment for any long period. The monotony of the environment also interferes with obtaining valuable information since there is no way of determining if the patient would prefer to do something else since he does not have the opportunity to change his activities; nor can his reactions to the varying stimuli produced by such changes in activity be ascertained.

Devising a new type research ward is an unorthodox and expensive project. We were

fortunate in finding a sponsor² with the imagination to invest “risk” capital in underwriting the cost of such construction.

In designing the ward we tried to circumvent some of the obstructions mentioned above. Our aim was to provide a ward in which we could:

1. Record behavior without the observer interacting with the patient;

2. Carry out our observations without the patient knowing when he was and when he was not being observed;

3. Follow the activities of a patient for as long as we chose;

4. Provide the patient with a choice of differing environments without loss of continuous observation;

5. Obtain information from the patient's reactions in each of the settings he could select;

6. Permanently record (on tape, silent film, or sound film) selected segments of behavior for later study;

7. Use our personnel with maximum efficiency to facilitate the accurate and complete collection of urine, feces and other specimens upon which the physiological and biochemical studies depend.

The purpose of the research should determine not only the construction of the ward, the techniques of observation but also the type of personnel and the selection of the patients. The ward about to be described was designed for multidisciplinary studies on chronic schizophrenic patients. The principles of patient selection have been described elsewhere⁽¹⁾ but also included a group of periodic catatonics.

Figures 1 and 2 respectively show the old and the new physical set-up. Figure 1 is typical of most wards in mental hospitals.

A frequent requirement of any research involving physiological measurements is the obtaining of temperature, pulse, respiration and blood pressure under standardized “basal” conditions. Our own requirement was that this be done on a t.i.d. basis with the patients lying quietly in bed for half

FIGURE 1

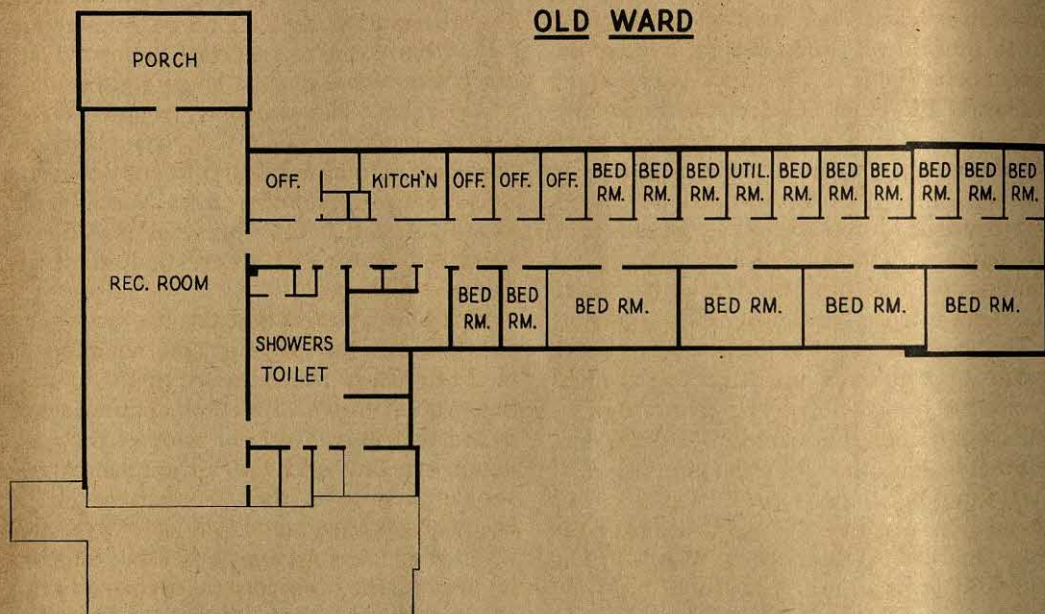

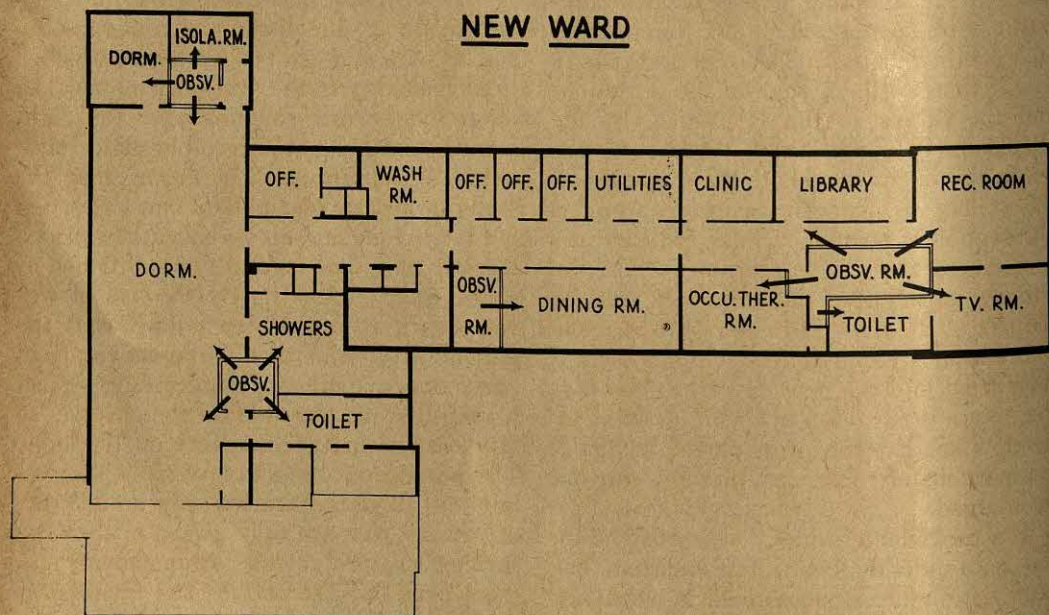

OLD WARD

FIGURE 2

NEW WARD

an hour in advance, but without sleeping. The way the ward was originally constructed it was virtually impossible to keep each of the patients under continuous observation since this would have required an extravagant number of ward personnel. The charting of medications, behavioral observations and other data further reduced the

number of persons available to follow the patients because of the location of the nurses' office where this was done.

In the reconstructed ward the day room has been converted to a dormitory which is separated by three semi-soundproof accordion partitions. This permits continuous observation of all the patients or, if desired, of a

smaller group only. In addition, the outside porch was closed off and an observation booth introduced, thus making two soundproof rooms housing 3 patients in one and 1 patient in the other. This makes it possible for even a patient who is in need of isolation because of an infectious condition or physical illness to be continued on the research ward. More especially, patients who are having metabolic studies carried out can be separated from the rest of the ward, and more intense basal observations taken.

The position of the observation booth makes it possible for one attendant at night to observe these two special rooms and, by pulling back all the soundproof partitions, to observe the other four sleeping areas. If the normal personnel ratio is available, two attendants are present; one in each of the areas marked "Observation Booth." The soundproof partitions can then be fully pulled out and three areas be under observation by each nurse or attendant. On rising in the morning it was formerly impossible to keep track of all the patients on a continuous basis. This was particularly true if some of them were in the dormitory and the others in the lavatories. In the "Rockland Research Ward" the observation booth also opens upon both the showers and the toilets so that the same continuous observation is possible. Under ordinary circumstances after their morning toilet, the patients move out of the dormitory area for the rest of the day. At breakfast they move into the next area and upon completing their meal into the new day area. The dining room is also set up with a one-way window so that the principle of having a non-participant observer present can be maintained.

The area which formerly was occupied by the semi-individual sleeping quarters has been thoroughly reconstructed in a manner that meets most of our research needs. There is now a large central observation station with one-way glass all around which contains the nurses office. Even the adjacent lavatory can be monitored, but the wall on this side of the observation station is closed and entrance from the observation room to the lavatory is through an interior door. This means that toilet privacy is not violated unless there is a specific re-

search demand. In addition to the lavatory the observation area monitors four rooms—the library, the recreational therapy room, the occupational therapy shop, and the television room. The two noisy rooms (recreational therapy and T.V.) have doors on them which may be closed to cut down the noise reaching the other areas. With even a minimum staff it then becomes possible to carry out reasonable observation of all patients at all times.

It is not expected that the one-way glass will deceive the patients and no effort is made to justify the existence of the central observation room. Research patients are aware that in one form or another they are under scrutiny and the advantage of the present system is that the patients have no way of knowing when they are and when they are not being observed. Similarly, because the observers are invisible to the patients they do not enter into the usual interactions.

All four rooms have been wired for sound and contain directional microphones installed with a two-way sound system which is controlled from the observation area. The microphones are contained in the light fixtures and are not detectable under ordinary circumstances. This means that the study of a particular patient can be carried out intensively and his verbalizations placed directly on a tape recorder or auditioned as they occur (or both). By the use of trip switches it is possible to follow what the patient says even though he moves from one room to another. The recording system is such that it is possible for the observer to also edit or make comments on the tape. The purpose of a research ward is observation and there must necessarily be invasion of privacy. We are fully aware of the "Big Brother" nature of the arrangement, but there exists no alternative. The invasion of the dermal limits of a person with a hypodermic needle injected into a blood vessel or into the spinal canal is done in order to obtain necessary information and not out of either morbid curiosity or an effort to exert "undue influence." Like most researchers, each member of our staff has a strong sense of his individuality, and our dislike of utilizing the "Big Brother" technique except out of necessity provides a real guar-

antee against its abuse.

The division of the daytime space into four rooms means that one can study the movements from one activity area to another, which is particularly useful as any change in place is up to the patient and can be correlated with other behavioral changes. The two-way sound system permits music or, if need be for research, "hallucinations" to be sent back to the patients.

The same difficulties we had experienced in the old ward with observation also held true for urine collection. At least 14 of our chronic regressed schizophrenic patients are on a continuous 24 hour urine collection regimen at any time. It is essential that collection be carefully carried out and that slip-ups be held to a minimum. This had usually been attempted by locking the door to the lavatory area; an attendant accompanied any patient who was a doubtful collector, insuring that he used his own container and did not discard it afterwards. Most of the patients, after a period of training, became good "collectors" and could be trusted to do this on their own. However, the difficult collectors at times did not even come to the toilet but found a quiet corner in which to urinate. The design of the new research ward makes such "accidents" less likely.

Another factor taken into consideration in the design of the ward was the prevalence of amebiasis in mental hospital patients (2). To this end, no patients are accepted on the research ward unless they have 6 negative stools for ameba, and even then they are treated for amebiasis for 6 days before they are brought to the research ward. The normal design of the lavatory area in most hospitals results in the showers being adjacent to the toilets with no intervening wall. The obvious advantage of this situation for the breeding of ameba led us to wall off these two areas from each other in the new research ward.

The plan outlined above is now completed and the patients have been trans-

ferred to the ward. It is of interest, though not unexpected, that the fears, criticism and dire predictions we ourselves (and others) had made turned out to be largely unfounded. Patients seem to pay little attention to the observation station and, if anything, were surprisingly indifferent.

SUMMARY

1. A new type research ward has been constructed at Rockland State Hospital.

2. The reasons why we felt it necessary to alter the existing ward are outlined, and the old and new plans shown.

3. Unique features of this new ward are described.

4. The above features are of significance to our researches at Rockland State Hospital, but the authors feel that the problems posed and the architectural solutions arrived at may be of value to other investigators since it permits:

- a) recording of patient's behavior without interaction with the observer;

- b) absence of knowledge of the patient as to when he is and when he is not being observed;

- c) observation for extended periods of time;

- d) patient selection of any of four different "environments" without loss of continuous observations by the observer;

- e) the recording of reactions in each of these environments;

- f) permanent recording (tape, silent film or sound film) of selected segments of behavior for later analysis;

- g) maximum utilization of available personnel which facilitates the accurate and complete collection of urine, feces and other specimens upon which physiological and biochemical studies depend.

PSYCHIATRIC HISTORY IN PSYCHIATRIC EDUCATION: REPORT OF A SURVEY

WILLIAM F. KNOFF, M.D.¹

History is a perennially neglected subject in medical and psychiatric education. The earliest American survey of the teaching of the history of medicine was that of Cordell, published in 1904(4). The author examined conditions in 14 universities and found that only three were offering full courses of 14 to 16 lectures in medical history. Nevertheless, Cordell predicted optimistically: "The time is near at hand when the standing of universities will be judged by their attitude to this branch, and when it will be assigned a front rank in the curriculum"(8).

Thirty-three years later, in the most recent authoritative survey—that of Sigerist in 1937(8)—the author observed that Cordell's postulates had not been fulfilled. Sigerist's questionnaire study in the late 'thirties revealed that 46 of 77 (60%) Grade A medical schools in the United States offered regular courses in medical history, that they were required in 28, with examinations in 22(3). Fifty-four (70%) provided some kind of instruction in medical history. More recently, in 1951, the Committee on the Teaching of Medical History of the American Association of the History of Medicine stated(3):

... it is frequently affirmed that the study and the teaching of medical history is on the increase. . . . Yet though the quality of the work may be superior, and the special laborers more competent, it remains true that the over-all, the average medical student and medical practitioner, is less well informed in the history of his profession than was his fore-runner of a century ago.

In 1957, Ackerknecht, commenting on the 1937 Sigerist study of undergraduate education, observed "... since 1937 . . . the situation regarding medical history has remained more or less stationary, and per-

haps even improved somewhat"(5). These observations pertain to the teaching of the history of medicine. Psychiatric history has been, at least until recently, part of medical history.

Turning now to post-graduate education in psychiatry, we find no traditional place for the teaching of psychiatric history in training center curricula. The report of the 1952 Conference on Psychiatric Education (1) does not mention psychiatric history specifically but alludes to it in the chapter entitled "Ideals and Practices" by recommending for the psychiatric resident "Knowledge of the development of psychiatric concepts and practices as they have emerged through observation, experience, and investigative procedures"(1). The section on "Basic Psychiatry" recommends "... Knowledge of psychopathology, including phenomenology or descriptive psychiatry with its historical perspectives"(1). This apparent lack of definitive interest in psychiatric history is not surprising, however, because emphasis upon the history of a discipline follows rather than precedes the establishment of that discipline. The publication of Zilboorg's monumental *A History of Medical Psychology*(9) in 1941, therefore, may be regarded as one indication of the establishment and recognition of psychiatry as a discipline. Of course, the history of medicine and the history of psychiatry are inextricably intertwined (as Zilboorg indicated in his title). One cannot teach one without teaching the other—nor can one inquire into the history of psychiatry without inquiring into the history of medicine. The more psychiatry "comes of age," however, the more its own history—its evolution as a body of knowledge—will be inquired into and taught. As Schneck points out in his recent *A History of Psychiatry*: "Departments of psychiatry in medical schools have expanded greatly during the past two decades. Medical educators agree generally on the importance of historical perspective in all branches of study"(7).

¹ Associate Professor, Dept. of Psychiatry, State University of New York, Upstate Medical Center, Syracuse, N. Y.

Undoubtedly, this process will continue. In order to see how it is going, we undertook, early in 1961, a questionnaire survey of attitudes and practices in the teaching of psychiatric history to residents in psychiatry.

Sampling. In order to obtain what we considered to be a "representative sample" of opinions from psychiatric training centers, we referred to the "Internship and Residency Number" of the *Journal of the American Medical Association* (6), and turned to the *Directory of Approved Residencies* listing 226 hospitals which have residency programs in psychiatry approved for 3 years of training. We decided not to try to survey all of the 226 hospitals listed (nor any 2-year programs), but to limit our sample to a convenient "round" number of 100, broken down as 90 U. S. residencies and 10 Canadian residencies. Addresses of 10 Canadian programs were selected, with one exception, from the April 2, 1960 issue of the *Canadian Medical Association Journal* (2). The programs we chose were not randomly selected. We included mostly major medi-

cal centers engaged in psychiatric teaching and general hospitals with large psychiatric training programs. Wide geographical distribution was achieved by including centers in 35 states and the District of Columbia as well as the Canadian centers. Unfortunately, we cannot list the 100 addresses we used because the letter accompanying the questionnaire committed us to confidentiality. It was our hope that this statement, and the stamped return envelope enclosed, would stimulate response. Actually, this seemed to be the case, inasmuch as 85 questionnaires were quite promptly returned—a very high percentage as questionnaire surveys go. Many respondents were generous with information about their approach to psychiatric history or their aspirations for course-work in the subject. Some contributed outlines or reading lists, and, a few, overviews of their training programs. In all, the response was most gratifying and we would like to express our appreciation here to all those who expended their time to fill out the questionnaire and to write to us. To the many

FIGURE 1

Dear Dr.

We would appreciate it very much if you would take five minutes of your time to answer the four questions on the attached questionnaire. In the interest of post-graduate psychiatric education, we are conducting an informal survey of one hundred training centers in an endeavor to evaluate the emphasis which is placed upon a particular aspect of psychiatry — the historical aspect — in their teaching curricula. (By way of definition, the term "historical aspect" might include information from any of various sources: History, Medical History, Psychiatric History, Intellectual History, History of Science, etc.)

Your answers will be held in confidence, and your participation is greatly appreciated.

A stamped return envelope is enclosed for your convenience.

Sincerely,

who requested information regarding the results of the survey, it is hoped that this paper will suffice.

The Questionnaire. Reproductions of the questionnaire and the "covering" letter which accompanied it are given in Figure 1 and Figure 2, which are self-explanatory. The questionnaire focused on *attitude* and *method* in regard to teaching the History of Psychiatry, without emphasizing *content* specifically. Question 2 inquires regarding a systematic course: if one is offered and how it is designed. Question 3 refers to integrated teaching, reminiscent of the so-called Oslerian method which made the clinical or pre-clinical teacher responsible for the presentation of the history of his own field.

Findings. One hundred questionnaires were circularized (90 to U. S. centers, 10 to

Canada). Eighty-five were returned (77 from the U. S., 8 from Canada). In the (1939) Sigerist study, 77 Grade A U. S. Medical Schools were circularized and 74 responded. Sigerist assumed that the 3 schools which did not reply were not much interested in teaching medical history. We are probably justified in making a similar assumption in regard to attitudes toward psychiatric history in the 15 non-replying centers in our study. We will present our collation, therefore, in two percentage columns on the face of the questionnaire itself: one based on the ideal sample (100) and one based on the real sample (85). The collation was made using the hand tally method (Fig. 3).

The most frequently encountered response (57%) is shown in Figure 4.

FIGURE 2 QUESTIONNAIRE

1. In what way do you regard a course in the history of psychiatry:
 - a) as essentially of academic interest only. ()
 - b) as largely for the purpose of Board examination. ()
 - c) as an important or essential part of the post-graduate (residency) curriculum. ()

(Please check appropriate answer(s).)
2. a) In the curriculum at your center, is a separate course devoted to the history of psychiatry? Yes () No ()
- b) If so, in what year of the program is it offered?
- Required or elective?
- How many hours?
- Conducted by (psychiatrist, historian)?
- Required reading? Yes () No ()
- Textbook (title)?
- c) Would you please send reading list, if available?
3. Rather than treating history as a separate subject, do you blend historical information with your presentation of current theories and techniques? Yes () No ()
4. Do you regard the historical, evolutionary perspective as so important that, more than blending, you present psychiatric theory and technique entirely in a historical frame of reference? Yes () No ()

Comments amplifying or modifying your answers will be greatly appreciated. These may be typed on the back of this sheet or on separate pages.

Thank you very much.

We came to view this pattern as the standard response (normative or "socially desirable") to this kind of questionnaire. Often this response was accompanied by comments expressing the respondent's aspiration to develop the area of psychiatric history or regret for not having yet done so.

SUMMARY

One hundred teaching centers in the U. S. and Canada were surveyed for attitudes and practices in regard to the teaching of the history of psychiatry; eighty-five responded. The "standard response" indicated a favorable attitude toward psychiatric his-

FIGURE 3

Thank you very much.

tory, and an effort to teach it by blending historical aspects with current material. (The *pros* and *cons* of methodology must be reserved for another paper.) Twenty-two of the U. S. centers surveyed, and 2 Canadian centers offer systematic courses in this subject to their residents. The average curriculum time devoted to history is 17 hours.² Sixty-four centers reported that they integrate historical information with their presentations of current theories and techniques.

² Sigerist regarded 12 hours as the minimum time for an undergraduate course in medical history(8). At present, in Syracuse, 40 hours are devoted to a course in psychiatric history for second year residents.

THE PSYCHIATRIST LOOKS AT PROFESSIONAL COURTESY¹

ALFRED AUERBACK, M.D.²

Physicians by tradition and custom do not charge fees to other physicians or members of their families for professional services. In recent years there has been a growing resentment towards psychiatrists because charges have been made when physicians or their dependents sought psychiatric help. Inquiries on this aspect of professional courtesy have been directed to the governing bodies of both the American Psychiatric Association and American Medical Association, and to many state and county medical societies. At times complaints have been made to the Ethics Committees of these medical groups and in some cases psychiatrists have been judged as being unethical because they charged other physicians for services.

The Executive Council of the APA has considered this matter in the past and made several decisions regarding it. In May 1953 the APA Council ruled: "That it be ethical for a physician (psychiatrist) to levy fees negotiated prior to treatment against a physician-patient or a member of his family, if the services involved are likely to be prolonged." A year later in May 1954 the Council "unanimously went on record as disapproving the making of charges by psychiatrists for single visits or for short term therapy in the cases of physicians or their immediate dependents." The Judicial Council of the AMA has consistently held that psychiatrists should not charge other physicians or their dependents for psychiatric treatment. As a result the governing bodies of the two medical associations to which most psychiatrists belong have differing rules regarding professional courtesy when physicians or their dependents seek psychiatric help. Inevitably confusion and misunderstanding have ensued and an increasing problem has developed between psychiatrists and physicians in other branches of medicine.
